Echinococcosis

Essentials of Diagnosis

- History of exposure to dogs or wild canines in an endemic area.
- Large cystic lesions, most commonly of the liver or lung.
- Positive serologic tests.

General Considerations

Echinococcosis occurs when humans are intermediate hosts for canine tapeworms. Infection is acquired by ingesting food contaminated with canine feces containing parasite eggs. The principal species that infect humans are *Echinococcus granulosus*, which causes cystic hydatid disease, and *Echinococcus multilocularis*, which causes alveolar hydatid disease. *E granulosus* is transmitted by domestic dogs in areas with livestock (sheep, goats, camels, and horses) as intermediate hosts, including Africa, the Middle East, southern Europe, South America, Central Asia, Australia, New Zealand, and the southwestern United States. *E multilocularis*, which much less commonly causes human disease, is transmitted by wild canines, and endemic in northern forest areas of the northern hemisphere, including central Europe, Siberia, northern Japan, northwestern Canada, and western Alaska. An increase in the fox population in Europe has been associated with an increase in human cases. The disease range has also extended southward in Central Asia and China. Other species that cause limited disease in humans are endemic in South America and China.

After humans ingest parasite eggs, the eggs hatch in the intestines to form oncospheres, which penetrate the mucosa, enter the circulation, and encyst in specific organs as hydatid cysts. *E granulosus* forms cysts most commonly in the liver (65%) and lungs (25%), but the cysts may develop in any organ, including the brain, bones, skeletal muscles, kidneys, and spleen. Cysts are most commonly single. The cysts can persist and slowly grow for many years (see illustration); (see illustration).

Fig.

Life cycle of *Echinococcus granulosus* (hydatid tapeworm). The normal intermediate host (sheep) and the occasional intermediate host (human) are shown in contact with the normal final host (dog). The human can become contaminated with tapeworm eggs in fecal matter in the dog's fur. Transmission in the normal way—predation of a herbivore by a carnivore—results in development of numerous adult tapeworms in the dog intestine and passage of eggs in the stool, followed by infection of a grazing sheep. ***1–6:*** An oncosphere hatches from an egg in the gut of a sheep or human (1). After penetration of the gut and development of a hydatid cyst in the liver (2), a daughter colony (3) is formed, with individual scoleces (hydatid sand) (4). Breaking of the cysts by the dog releases numerous scoleces, which are ingested and evert in the dog intestine (5), subsequently growing into adult worms, which produce viable eggs (6) that are passed in the dog's feces to contaminate fur or grass—the source of infection for humans and sheep. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Fig.

Life cycle of *Echinococcus multilocularis* (agent of alveolar [multiloculated] hydatidosis). The normal intermediate hosts are microtine rodents (voles); rarely, humans–typically an Eskimo fur trapper–become intermediate hosts. Ingestion of an infected vole by a fox, the normal final host, results in breakup of the alveolar hydatid in the fox gut, release of individual scoleces, and growth of the minute adult tapeworms, followed by passage of worm eggs in fox feces and exposure of human trappers who handle fecally soiled fox furs. ***1–3:*** An oncosphere (1) is released in the gut from an egg ingested by the intermediate host. The oncosphere penetrates the gut and develops into an alveolar (multiloculated) hydatid cyst (2), usually fatal to the human and debilitating to the vole, making the rodent easy prey for the fox. Adult worms in the fox intestine release eggs (3) that pass to the grass or are caught in the fur to serve as a source of infection of rodent or human intermediate hosts. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Clinical Findings

Symptoms and Signs

Infections are commonly asymptomatic and may be noted incidentally on imaging studies or present with symptoms caused by an enlarging or superinfected mass. Findings may include abdominal or chest pain, biliary obstruction, cholangitis, portal hypertension, cirrhosis, bronchial obstruction leading to segmental lung collapse, and abscesses. Cyst leakage or rupture may be accompanied by a severe allergic reaction, including fever and hypotension. Seeding of cysts after rupture may extend the infection to new areas (see x-ray); (see CT scan).

Fig.

Chest x-ray of 19-year-old man showing a recently ruptured hydatid cyst in the right lung. Note fluid level (arrows). (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Fig.

Abdominal CT scan of a patient with an *Echinococcus multilocularis* lesion in the right lobe of the liver. Note irregular low-density zones alternating with scattered areas of calcification. (Courtesy of JF Wilson.)

E multilocularis generally causes a more aggressive disease than *E granulosus*, with initial infection of the liver, but then local and distant spread commonly suggesting a malignancy. Symptoms based on the areas of involvement gradually worsen over years, with the development of obstructive findings in the liver and elsewhere.

Laboratory Findings

Serologic tests, including ELISA and immunoblot, offer sensitivity and specificity over 80% for *E granulosus* liver infections, but lower sensitivity for involvement of other organs. Serologic tests may also distinguish the two major echinococcal infections.

Imaging

Diagnosis is usually based on imaging studies, including ultrasonography, CT, and MRI (see CT scan); (see CT scan). In *E granulosus* infection, a large cyst containing daughter cysts is highly suggestive of the diagnosis. In *E multilocularis* infection, imaging shows an irregular mass, often with areas of calcification.

Fig.
Echinococcosis of the liver with hepatobronchial fistula. This CT scan of the upper portion of the liver demonstrates a large, well-circumscribed, sharply

demarcated cystic lesion of the right lobe of the liver near the diaphragm—typical of echinococcal cysts. The additional finding here is a change in the right lung at the posterior sulcus so that instead of the lung around the cyst being aerated, there is increased density within this area. This finding proved to be the result of a fistula from the echinococcal cyst through the diaphragm and into the right lung base. (Courtesy of H Goldberg.)

Fig.

Abdominal CT scan showing a large primary hydatid cyst (*Echinococcus granulosus*) in the right lobe of the liver. Note multiple internal septations indicating secondary (daughter) cyst formation. (Courtesy of P Braithwaite.)

Treatment

Treatment of cystic hydatid disease has traditionally involved cautious surgical resection of cysts, with care not to rupture cysts during removal. Injection of a cysticidal agent was used to limit spread in the case of rupture. Recently, new management algorithms include treatment with albendazole, often in conjunction with surgery. When used alone, as in cases where surgery is not possible, albendazole (10–15 mg/kg/d orally) has demonstrated efficacy, with courses of 3 months or longer duration, in some cases with alternating cycles of treatment and rest. Mebendazole (40–50 mg/kg/d orally) is an alternative drug, and praziquantel may also be effective. In some cases, medical therapy is begun, with surgery performed if disease persists after some months of therapy. Another approach, in particular with inoperable cysts, is percutaneous aspiration, injection, and reaspiration (PAIR). In this approach (which should not be used if cysts communicate with the biliary tract), patients receive antihelminthic therapy, and the cyst is partially aspirated. After diagnostic confirmation by examination for parasite protoscolices, a scolicidal agent (such as 95% ethanol or 0.5% cetrimide) is injected. Treatment of alveolar cyst disease is challenging, generally relying on wide surgical resection of lesions. Therapy with albendazole before or during surgery may be beneficial and may also provide improvement or even cure in inoperable cases.

Other Invasive Cestode Infections

Ingestion of aquatic copepods infected with larvae of *Spirometra* canine or feline tapeworms can lead to sparganosis, especially in South America and East Asia. Infection can also come from ingestion of undercooked infected meat (including mammals, birds, reptiles, and amphibians) or from use of frog or snake-meat poultices. The worms penetrate the intestinal wall or skin and migrate to various tissues. Inflammatory lesions, most commonly of the skin or eyes, are typically present. In cerebral sparganosis, an intense inflammatory response to worms can lead to severe neurologic disease. Diagnosis is by biopsy or visualization of the parasite. Treatment consists of surgical resection or local injection of ethanol. Antihelminthics do not appear to be helpful. Other non-human tapeworms can also cause localized and CNS inflammatory lesions. These are also managed with surgical resection.

Ascariasis

Essentials of Diagnosis

- Transient cough, urticaria, pulmonary infiltrates, eosinophilia.
- Nonspecific abdominal symptoms.
- Eggs in stool; adult worms occasionally passed.

Ascaris lumbricoides is the most common of the intestinal helminths, infecting about a quarter of the world's population, with estimates of over a billion infections, 12 million acute cases, and 10,000 or more deaths annually. Prevalence is high wherever there is poor hygiene and sanitation or where human feces are used as fertilizer. Heavy infections are most common in children.

Infection follows ingestion of eggs in contaminated food. Larvae hatch in the small intestine, penetrate into the bloodstream, migrate to the lungs, and then travel via airways back to the gastrointestinal tract, where they develop to adult worms, which can be up to 40 cm in length, and live for 1–2 years (see illustration).

Fig.

Life cycle of *Ascaris lumbricoides* (the giant roundworm of humans). Infection occurs from ingestion of *Ascaris* eggs on vegetables and other foods eaten raw that have been contaminated with feces from infected humans. Infective eggs hatch in the duodenum, penetrate the gut, pass in blood vessels to the lungs, and break out into alveoli, where they molt and in about a week are carried up the bronchioles, bronchi, and trachea to the mouth. They are then swallowed and return to the small intestine, where the worms mature and survive about 1 year. ***1–7:*** Second-stage larvae emerge from an ingested egg (1). In (2) is shown the anterior tip of an adult worm with a typical ascarid arrangement of three lips around a tripartite mouth. A mated pair of ascarids (3) is seen in the small intestine. The posterior tip of the male in (4) shows a projecting pair of copulatory spicules. The sectional view of an undeveloped egg in (5) shows the heavy protective shell—this is the developmental stage usually passed in human feces. An egg in soil with developing larva is shown in (6), and in (7) is shown a mature infective egg after 3–6 weeks. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Clinical Findings

Most persons with *Ascaris* infection are asymptomatic. A small proportion develop symptoms during migration of worms through the lungs, with fever, nonproductive cough, chest pain, dyspnea, and eosinophilia, occasionally with eosinophilic pneumonia. Rarely, larvae lodge ectopically in the brain, kidney, eye, spinal cord, and other sites and may cause local symptoms.

Light intestinal infections usually produce no symptoms. With heavy infection, abdominal discomfort may be seen. Adult worms may also migrate and be coughed up, be vomited, or may emerge through the nose or anus. They may also migrate into the common bile duct, pancreatic duct, appendix, and other sites, which may lead to cholangitis, cholecystitis, pyogenic liver abscess, pancreatitis, obstructive jaundice, or appendicitis. With very heavy infestations, masses of worms may cause intestinal obstruction, volvulus, intussusception, or death.

Although severe manifestations of infection are uncommon, the very high prevalence of ascariasis leads to large numbers of individuals, especially children, with important sequelae. Moderate to high worm loads in children are also associated with nutritional abnormalities due to decreased appetite and food intake, and also decreased absorption of nutrients.

The diagnosis of ascariasis is made after adult worms emerge from the mouth, nose, or anus, or by identifying characteristic eggs in the feces. Due to the very high egg burden, concentration techniques are generally not needed. Imaging studies demonstrate worms, with filling defects in contrast studies and at times evidence of intestinal or biliary obstruction. Eosinophilia is marked during worm migration but may be absent during intestinal infection.

Treatment

All infections should ideally be treated. Treatments of choice are albendazole (single 400 mg oral dose), mebendazole (single 500 mg oral dose or 100 mg twice daily for 3 days), or pyrantel pamoate (single 11 mg/kg oral dose, maximum 1 g). These drugs are all well tolerated but may cause mild gastrointestinal toxicity. They are now considered safe for children above 1 year of age and in pregnancy, although use in the first trimester is best avoided. Intestinal obstruction usually responds to conservative management and antihelminthic therapy. Surgery may be required for appendicitis and other gastrointestinal complications.

Trichuriasis

Trichuris trichiura, the whipworm, infects about a billion persons throughout the world, particularly in humid tropical and subtropical environments. Infection is heaviest and most frequent in children. Infections are acquired by ingestion of eggs. The larvae hatch in the small intestine and mature in the large bowel to adult worms of about 4 cm in length (see illustration). The worms do not migrate through tissues (see illustration).

Fig.

Trichuris trichiura. Note copulatory bursa and single terminal spicule in male (above). Female at right. The worms inhabit the large intestine, with their narrow anterior ends sewn into the mucosa. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Fig.

Life cycle of *Trichuris trichiura*. After ingestion of contaminated food by the host, eggs hatch in the duodenum (1), releasing larvae that pass to the large bowel, where the worms mature (2). Heavy infection of the lower colon may induce anal prolapse. Normally, eggs (3) pass in feces, mature in soil in about 6 weeks (4), and contaminate soil, fingers, or food for transmission to another human. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Most infected persons are asymptomatic. Heavy infections may be accompanied by abdominal cramps, tenesmus, diarrhea, distention, nausea, and vomiting. The *Trichuris* dysentery syndrome may develop, particularly in malnourished young children, with findings resembling inflammatory bowel disease including bloody diarrhea and rectal prolapse. Chronic infections in children can lead to iron deficiency anemia, growth retardation, and clubbing of the fingers.

Trichuriasis is diagnosed by identification of characteristic eggs and sometimes adult worms in stools. Concentration techniques are not needed. Eosinophilia is common. Treatment is with albendazole (400 mg/d orally) or mebendazole (200 mg/d orally), for 1–3 days for light infections or 3–7 days for heavy infections.

Hookworm Disease

Essentials of Diagnosis

- Transient pruritic skin rash and pulmonary symptoms.
- Anorexia, diarrhea, abdominal discomfort.
- Iron deficiency anemia.
- Characteristic eggs and occult blood in the stool.

General Considerations

Infection with the hookworms *Ancylostoma duodenale* and *Necator americanus* is very common, especially in most tropical and subtropical regions. Both worms are broadly distributed. Prevalence is estimated at about 1 billion, causing approximately 65,000 deaths each year. When eggs are deposited on warm moist soil they hatch, releasing larvae that remain infective for up to a week. With contact, the larvae penetrate skin and migrate in the bloodstream to the pulmonary capillaries. In the lungs, the larvae penetrate into alveoli and then are carried by ciliary action upward to the bronchi, trachea, and mouth. After being swallowed, they reach and attach to the mucosa of the upper small bowel, where they mature to adult worms. *Ancylostoma* infection can also be acquired by ingestion of the larvae in food or water. Hookworms attach to the intestinal mucosa and suck blood. Blood loss is proportionate to the worm burden (see illustration); (see photograph).

Fig.

Life cycles of *Ancylostoma duodenale* and *Necator americanus* (human hookworms). Penetration of the skin by infective hookworm larvae is followed by migration of larvae from the skin, through the bloodstream to the heart and lungs, and then via the bronchi, trachea, and mouth to the intestine, where the bloodsucking worms pair, mate, and release eggs in feces. ***1–6:*** In (1), a pair of copulating adult worms is shown attached to the intestinal mucosa. An egg at the tetranucleated stage (2) is passed in feces. In (3) is shown an embryonated egg prior to hatching in soil. Rhabditiform larvae in soil (4) molt to produce infective filariform larvae, still loosely covered by the protective second-stage larval sheath (5). The infective larvae rapidly respond to nearby human skin, become extremely active, and penetrate the skin upon contact (6). (Reproduced, with permission, from Goldsmith R,

Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Fig.

(Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Clinical Findings

Symptoms and Signs

Most infected persons are asymptomatic. A pruritic maculopapular rash (ground itch) may occur at the site of larval penetration, usually in previously sensitized persons. Pulmonary symptoms may be seen during larval migration through the lungs, with dry cough, wheezing, and low-grade fever, but these symptoms are less common than with ascariasis. Eosinophilia is common, especially during worm migration. About 1 month after infection, as maturing worms attach to the small intestinal mucosa, gastrointestinal symptoms may develop, with epigastric pain, anorexia, and diarrhea, especially in previously unexposed individuals. Persons chronically infected with large worm burdens may have abdominal pain, anorexia, diarrhea, and findings of marked iron-deficiency anemia and protein malnutrition. Anemia can lead to pallor, weakness, dyspnea, and congestive heart failure, and protein loss can lead to hypoalbuminemia, edema, and ascites. These findings may be accompanied by impairment in growth and cognitive development in children. Infection with the dog hookworm *Ancylostomacaninum* can uncommonly lead to abdominal pain, diarrhea, and eosinophilia, with intestinal ulcerations and regional lymphadenitis.

Laboratory Findings

Diagnosis is based on the demonstration of characteristic eggs in feces; concentration techniques are usually not needed (see illustration). Microcytic anemia, occult blood in the stool, hypoalbuminemia, and eosinophilia are common.

Fig.

Human hookworms. *Ancylostoma duodenale* and *Necator americanus* . ***Panel 1:*** Dorsal view of head, showing gripping teeth (*Ancylostoma*) and cutting plates (*Necator*). ***Panel 2:*** Male tails showing typical arrangement of the muscular lateral rays and spicules of *Ancylostoma* and *Necator* . ***Panel 3:*** Adult worms (female at left, male at right) in each pair. ***Panel 4:*** Developmental series showing an egg from the tetranucleated stage when laid to a larva ready for hatching in the soil after 1–2 days. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Treatment

Treatment is with albendazole (single 400 mg oral dose) or mebendazole (100 mg orally twice daily for 3 days). These drugs are teratogenic, but experience suggests that they are safe in children over 1 year of age and during the second and third trimesters of pregnancy. Occasional adverse effects are diarrhea and abdominal pain. Pyrantel pamoate and levamisole are also effective. Anemia should be managed with iron replacement and, for severe symptomatic anemia, blood transfusion. Mass treatment of children with single doses of albendazole or mebendazole at regular intervals limits worm burdens and the extent of disease and is advocated by the WHO.

Strongyloidiasis

Essentials of Diagnosis

- Transient pruritic skin rash and pulmonary symptoms.
- Anorexia, diarrhea, abdominal discomfort.
- Hyperinfection syndrome with varied severe presentations in the immunocompromised.
- Larvae detected in stool.
- With hyperinfection, larvae detected in sputum or other fluids.
- Eosinophilia.

General Considerations

Strongyloidiasis is caused by infection with *Strongyloides stercoralis.* Although much less prevalent than ascariasis, trichuriasis, or hookworm infections, strongyloidiasis is nonetheless a significant problem, infecting tens of millions of individuals in tropical and subtropical regions. Infection is also endemic in some temperate regions of North America, Europe, Japan, and Australia. Of particular importance is the predilection of the parasite to cause severe infections in immunocompromised individuals due to its ability to replicate in humans. A related parasite, *Strongyloides fuelleborni*, infects humans in parts of Africa and New Guinea.

Among nematodes, *S stercoralis* is uniquely capable of maintaining its full life cycle both within the human host and in soil (see illustration). Infection occurs when filariform larvae in soil penetrate the skin, enter the bloodstream, and are carried to the lungs, where they escape from capillaries into alveoli, ascend the bronchial tree, and are then swallowed and carried to the duodenum and upper jejunum, where maturation to the adult stage takes place. Females live embedded in the mucosa for up to 5 years, releasing eggs that hatch in the intestines (see photograph) as free rhabditiform larvae that pass to the ground via the feces. In moist soil, these larvae metamorphose into infective filariform larvae. Autoinfection can occur in humans, when some rhabditiform larvae develop into filariform larvae that penetrate the intestinal mucosa or perianal skin, and enter the circulation.

Fig.

Life cycle of *Strongyloides stercoralis* (small roundworm of humans). After penetration of the skin, infective larvae migrate via the bloodstream through the heart, lungs, trachea, and mouth to the intestine, where maturation of worms occurs in mucosa. Eggs laid in the mucosa hatch to rhabditiform larvae, which pass to soil in feces. ***1–3: Autoreinfection cycle*** . An adult parthenogenetic female produces eggs that hatch to rhabditiform larvae, which molt in gut and directly change to infective filariform larvae, which penetrate the gut locally and migrate via the bloodstream to autoreinfect the host, becoming reestablished in the gut. ***4–8: Indirect, free-living cycle*** . Rhabditiform larvae, passed in feces to soil, molt through successive stages to adults whose eggs hatch and then continue through a second or perhaps a third cycle. With drying of the soil, rhabditiform larvae molt to form infective filariform larvae (7) to reestablish the parasitic cycle by skin penetration. Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Clinical Findings

Symptoms and Signs

As with other intestinal nematodes, most infected persons are asymptomatic. An acute syndrome can be seen at the time of infection, with a pruritic, erythematous, maculopapular rash, usually of the feet. These symptoms may be followed by pulmonary symptoms (including dry cough, dyspnea, and wheezing) and eosinophilia after a number of days, followed by gastrointestinal symptoms after some weeks, as with hookworm infections. Chronic infection may be accompanied by epigastric pain, nausea, diarrhea, and anemia. Maculopapular or urticarial rashes of the buttocks, perineum, and thighs, due to migrating larvae, may be seen. Large worm burdens can lead to malabsorption or intestinal obstruction. Eosinophilia is common but may fluctuate.

The most dangerous manifestation of *S stercoralis* infection is the **hyperinfection syndrome,** with dissemination of large numbers of filariform larvae to the lungs and other tissues in immunocompromised individuals. Mortality with this syndrome approaches

100% without treatment and has been about 25% with treatment. The hyperinfection syndrome is seen in those receiving corticosteroids and other immunosuppressive medications, those with hematologic malignancies, malnutrition, or alcoholism, or those with AIDS. The risk seems greatest for those receiving corticosteroids, and considering the large number of at risk individuals, the risk in those with AIDS seems relatively low. With hyperinfection large numbers of larvae can migrate to many tissues, including the lungs, CNS, kidneys, and liver. Gastrointestinal symptoms can include abdominal pain, nausea, vomiting, diarrhea, and more severe findings related to intestinal obstruction, perforation, or hemorrhage. Bacterial sepsis, probably secondary to intestinal ulcerations, is a common presenting finding. Pulmonary findings include pneumonitis, cough, hemoptysis, and respiratory failure. Sputum may contain adult worms, larvae, and eggs. CNS disease includes meningitis and brain abscesses; the CSF may contain larvae. Various presentations can progress to shock and death.

Laboratory Findings

The diagnosis of strongyloidiasis can be difficult, as eggs are seldom found in feces. Diagnosis is usually based on the identification of rhabditiform larvae in the stool or duodenal contents. These larvae must be distinguished from hookworm larvae, which may hatch after stool collection (see photograph). Repeated examinations of stool or examination of duodenal fluid may be required for diagnosis because the sensitivity of individual tests is only about 30%. Hyperinfection is diagnosed by the identification of large numbers of larvae in stool, sputum, or other body fluids. An ELISA from the CDC offers about 90% sensitivity and specificity, but cross-reactions with other helminths may occur. Eosinophilia and mild anemia are common, but eosinophilia may be absent with hyperinfection. Hyperinfection may include extensive pulmonary infiltrates, hypoproteinemia, and abnormal liver function studies.

(Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Treatment

Full eradication of *S stercoralis* is more important than with other intestinal helminths due to the ability of the parasite to replicate in humans. The treatment of choice for routine infection is ivermectin (200 mcg orally daily for 1–2 days). This treatment has replaced thiabendazole (25 mg/kg orally twice daily for 3 days), which is relatively poorly tolerated, and albendazole (400 mg orally twice daily for 3 days), which is less effective. For hyperinfection, ivermectin should be administered daily until the clinical syndrome has resolved and larvae have not been identified for at least 2 weeks. Follow-up examinations for larvae in stool or sputum are necessary, with repeat dosing if the infection persists. With continued immunosuppression, eradication may be difficult, and regular repeated doses of antihelminthic therapy (eg, monthly ivermectin) may be required. It is important to be aware of the possibility of strongyloidiasis in those with even a distant history of residence in an endemic area, since the infection can be maintained for decades. Screening of at-risk individuals for infection is appropriate before institution of immunosuppressive therapy. Screening can consist of serologic tests, with stool examinations in those with positive serologic tests, but consideration of presumptive treatment even if the stool evaluations are negative.

Enterobiasis

Essentials of Diagnosis

- Nocturnal perianal pruritus.
- Identification of eggs or adult worms on perianal skin or in stool.

General Considerations

Enterobius vermicularis, the pinworm, is a common cause of intestinal infections worldwide, with maximal prevalence in school-age children. Enterobiasis is transmitted person-to-person via ingestion of eggs after contact with the hands or perianal region of an infected individual, food or fomites that have been contaminated by an infected individual, or infected bedding or clothing. Autoinfection also occurs. Eggs hatch in the duodenum and larvae migrate to the cecum. Females mature in about a month, and remain viable for about another month. During this time they migrate through the anus to deposit large numbers of eggs on the perianal skin. Due to the relatively short lifespan of these helminths, continuous reinfection, as in institutional settings, is required, for long-standing infection (see illustration).

Fig.

Life cycle of *Enterobius vermicularis* (pinworm). Infection is acquired by ingestion of eggs from fecally contaminated bedclothing or from scratching the anal area where eggs are deposited. ***1–3:*** Eggs hatch in the duodenum (1), and larvae migrate in the intestinal lumen and mature in the terminal portion of the large bowel. Adult worms pictured at right (2) show the smaller male with a curved tail. Egg-laying females emerge at night through the anus to deposit eggs on perianal skin. In (3), an egg containing a formed larva is visible shortly after being laid on the skin. The egg becomes infective in 4–6 hours. Clinical Findings

Symptoms and Signs

Most individuals with pinworm infection are asymptomatic. The most common symptom is perianal pruritus, particularly at night, due to the presence of the female worms or deposited eggs. Insomnia, restlessness, and enuresis are common in children. Perianal scratching may result in excoriation and impetigo. Many mild gastrointestinal symptoms have also been attributed to enterobiasis, but associations are not proven. Serious sequelae are uncommon. Rarely, worm migration results in inflammation or granulomatous reactions of the gastrointestinal or genitourinary tracts. Colonic ulceration and eosinophilic colitis have been reported.

Laboratory Findings

Pinworm eggs are usually not found in stool. Diagnosis is made by finding adult worms or eggs on the perianal skin (see illustration). A common test is to apply clear cellophane tape to the perianal skin, ideally in the early morning, followed by microscopic examination for eggs. The sensitivity of the tape test is reported to be about 50% for a single test and 90% for three tests. Nocturnal examination of the perianal area or gross examination of stools may reveal adult worms, which are about 1 cm in length. Eosinophilia is rare.

Treatment

Treatment is with single oral doses of albendazole (400 mg), mebendazole (100 mg) or pyrantel pamoate (11 mg/kg, to a maximum of 1 g). The dose is repeated in 2 weeks due to frequent reinfection. Other infected family members should be treated concurrently, and treatment of all close contacts may be appropriate when rates of reinfection are high in family, school, or institutional settings. Standard handwashing and hygiene practices are helpful in limiting spread. Perianal scratching should be discouraged. Washing of clothes and bedding should kill pinworm eggs.

Dracunculiasis

Essentials of Diagnosis

- Tender cutaneous ulcer and worm protruding from the skin of an individual who has ingested untreated water in rural Africa.

General Considerations

Dracunculiasis is caused by the nematode *Dracunculus medinensis*, or Guinea worm. It causes chronic cutaneous ulcers with protruding worms in rural Africa. It occurs only in humans and is a major cause of disability, although recent control efforts have been remarkably successful, with decreased annual incidence from about 3.5 million cases in the late 1980s to under 10,000 reported cases in 2007. Dracunculiasis has been eradicated from Asia, but remains endemic in 11 countries in West and Northeast Africa, most notably in southern Sudan. The disease occurs almost exclusively in isolated rural areas; all ages are affected, and prevalence may reach 60%.

Infection occurs after swallowing water containing the infected intermediate host, the crustacean *Cyclops* (known as copepods or water fleas). In the stomach, larvae escape from the copepods, and migrate through the intestinal mucosa to the retroperitoneum, where mating occurs. Females then migrate to subcutaneous tissue, usually of the legs, over about a year. A subcutaneous ulcer then forms. Upon contact with water, the parasite discharges large numbers of larvae, which are ingested by copepods (see photograph). Adult worms, which can be up to a meter in length, are gradually extruded. Worm death and disintegration in tissue may provoke a severe inflammatory reaction (see illustration).

Fig.

Worm blister caused by the head of a female guinea worm (*Dracunculus medinensis*). (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Fig.

Life cycle of *Dracunculus medinensis* (guinea worm). Infection is acquired from drinking water contaminated with infected copepods. The infection develops intraperitoneally, and an adult fertilized female migrates to the skin—especially to the legs—where a blister is induced around the head of the worm (the location of a uterine pore). When the part is immersed, the blister bursts, and the head of the worm emerges, resulting in release of thousands of larvae, which are ingested by a copepod, in which they grow and develop to the infective stage. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and*

Parasitology. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Clinical Findings

Patients are usually asymptomatic until the time of worm extrusion. At that time a painful papule develops, with erythema, pruritus, and burning, usually on the lower leg. Multiple lesions may be present. At this time, some patients may also develop a short-lived systemic reaction, which may include fever, urticaria, nausea, vomiting, diarrhea, and dyspnea. The skin lesion vesiculates over a few days, followed by ulceration. The ulcer is tender, often with a visible worm. The worm is then extruded or absorbed over a few weeks, followed by ulcer healing. Secondary infections, including infectious arthritis and tetanus, are common. The disease causes significant disability; lesions commonly prevent walking for a month or more.

Diagnosis follows identification of a typical skin ulcer with a protruding worm. When the worm is not visible, larvae may be identified on smears or seen after immersion in cold water. Eosinophilia is usually present.

Treatment

No drug cures the infection, but metronidazole and mebendazole are sometimes used to limit inflammation and facilitate worm removal. Wet compresses may relieve discomfort. Occlusive dressings improve hygiene and limit shedding of infectious larvae. Worms are typically removed by sequentially rolling them out over a small stick. When available, simple surgical procedures can be used to remove worms. Corticosteroid ointments may hasten healing. Topical antibiotics may limit bacterial superinfection.

Prevention

Dracunculiasis has proven to be easier to control than most parasitic infections. The disease is prevented by avoidance of contaminated drinking water. This can be accomplished by boiling, chlorination, or filtration through finely woven cloth. A WHO dracunculiasis eradication program, initiated in 1986, has been highly successful.

Trichinosis

Essentials of Diagnosis

- Ingestion of inadequately cooked pork or game.
- Transient intestinal symptoms followed by fever, myalgias, and periorbital edema.
- Eosinophilia and elevated serum muscle enzymes.

General Considerations

Trichinosis (or trichinellosis) is caused worldwide by *Trichinella spiralis* and related *Trichinella* species. The disease is spread by ingestion of undercooked meat, most commonly pork in areas where pigs feed on garbage. When infected raw meat is ingested, *Trichinella* larvae are freed from cyst walls by gastric acid and pass into the small intestine. The larvae then invade intestinal epithelial cells, develop into adults, and the adults release infective larvae. These parasites travel to skeletal muscle via the bloodstream. They invade muscle cells, enlarge, and form cysts. These larvae may be viable for years. Pigs and other animals become infected by eating infected uncooked food scraps or other animals, such as rats.

The worldwide incidence of trichinosis has decreased, but human infections continue to occur sporadically or in outbreaks. In addition to undercooked pork, infections have been transmitted by ingestion of game and other animals, including bear and walrus in North America and wild boar and horse in Europe. In the United States, about 100 infections are reported annually, about three-fourths from pork and the remainder from game animals (see illustration).

Fig.

Life cycle of *Trichinella spiralis* (trichina worm). Pigs become infected from eating uncooked garbage containing raw infected meat or occasionally from eating infected rats. Humans most commonly acquire the infection from undercooked pork. Polar bears often are infected from seal prey, and the seals presumably from infected carrion. Many such predator-prey cycles can account for transmission of this nonspecific nematode. Symptoms of infection (orbital and other sites of edema, muscle pain, eosinophilia) occur during the period of invasion of muscle tissue, 2–6 weeks after human ingestion of contaminated meat. ***1–4:*** Larvae digested from cysts (1) enter the mucosa, develop to adults in 3–4 days, and then return to the lumen and mate. The fertile females return to the mucosa and pass motile embryos (2) that enter the bloodstream and migrate to tissues. A larva leaves its blood vessel and enters a muscle fiber, which it modifies to a "nurse cell" (3). A few days later, it encysts within the modified muscle cell (4).

(Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Clinical Findings

Symptoms and Signs

Most infections are asymptomatic. In symptomatic cases, gastrointestinal symptoms, including diarrhea, vomiting, and abdominal pain, develop within the week after ingestion of contaminated meat. These symptoms usually last for less than a week but can occasionally persist for much longer. During the following week, symptoms and signs related to migrating larvae are seen. These findings include, most notably, fever, myalgias, periorbital edema, and eosinophilia. Additional findings may include headache, cough, dyspnea, hoarseness, dysphagia, macular or petechial rash, and subconjunctival and retinal hemorrhages. Systemic symptoms usually peak within 2–3 weeks, and commonly persist for about 2 months. In severe cases, generally with large parasite burdens, muscle involvement can be pronounced, with severe muscle pain, edema, and weakness, especially in the head and neck. Muscle pain may persist for months. Uncommon severe findings include myocarditis, pneumonitis, and meningoencephalitis, sometimes leading to death.

Laboratory Findings

The clinical diagnosis is supported by findings of elevated serum muscle enzymes (creatine kinase, lactate dehydrogenase, aspartate aminotransferase). Serologic tests become positive 3 or more weeks after infection; a variety of techniques are used, including ELISA, immunofluorescence, indirect hemagglutinin, precipitin, and bentonite flocculation assays. Rising antibody titers are highly suggestive of the diagnosis. Muscle biopsy can usually be avoided, but if the diagnosis is uncertain, biopsy of a tender, swollen muscle may identify *Trichinella* larvae. For maximal yield, biopsy material should be examined histologically, and a portion should be enzymatically digested to release larvae, but evaluation before about 3 weeks after infection may not show muscle larvae (see micrograph).

Fig.

Trichinella spiralis ***A:*** Penetration of muscle "nurse cell". ***B:*** Cyst digested free from host muscle, showing coiled larva. ***C:*** Cyst with pigmented granules visible at either end. ***D:*** Older cysts showing start of calcification, though larvae are still alive and viable. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Treatment

No effective specific therapy for full-blown trichinosis has been identified. However, if infection is suspected early in the course of illness, treatment with mebendazole (2.5 mg/kg orally twice daily) or albendazole (5–7.5 mg/kg orally twice daily) will kill intestinal worms and may limit progression to tissue invasion. Supportive therapy for systemic disease consists of analgesics, antipyretics, bed rest and, in severe illness, corticosteroids. Disease is prevented by adequate cooking or long-term freezing of pork and game. Irradiation of meat is also effective in eliminating *Trichinella* larvae.

Angiostrongyliasis

Nematodes of rats of the genus *Angiostrongylus* cause two distinct syndromes in humans. *Angiostrongylus cantonensis*, the rat lungworm, causes eosinophilic meningoencephalitis, primarily in Southeast Asia and some Pacific islands. *Angiostrongylus costaricensis* causes gastrointestinal inflammation. In both diseases, human infection follows ingestion of larvae within slugs or snails (and also crabs or prawns for *A cantonensis*) or on material contaminated by these organisms. Since the parasites are not in their natural hosts, they cannot complete their life cycles, but they can cause disease after migrating to the brain or gastrointestinal tract.

In *A cantonensis* infection, disease appears to be caused primarily by worm larvae migrating through the CNS and an inflammatory response to dying worms. After an incubation period of 1 day to 2 weeks, presenting symptoms and signs include headache, stiff neck, nausea, vomiting, cranial nerve abnormalities, and paresthesias.

Most cases resolve spontaneously after 2–8 weeks, but serious sequelae and death have been reported. The diagnosis is strongly suggested by the finding of eosinophilic CSF pleocytosis (leukocytosis with over 10% eosinophils) in a patient with a history of travel to an endemic area. Peripheral eosinophilia may not be present. A cantonensis larvae have rarely been recovered from the CSF and the eyes. There is no specific treatment. Antihelminthic therapy is probably not indicated, since responses to dying worms may worsen with therapy. Corticosteroids have been used in severe cases.

In *A costaricensis* infection, parasites penetrate ileocecal vasculature and develop into adults, which lay eggs, but do not complete their life cycle. Disease is due to an inflammatory response to dying worms in the intestinal tract, with an eosinophilic granulomatous response, at times including vasculitis and ischemic necrosis. Common findings are abdominal pain, vomiting, and fever. Pain is most commonly localized to the right lower quadrant, and a mass may be appreciated, all mimicking appendicitis. Symptoms may recur over months. Uncommon findings are intestinal perforation or obstruction, or disease due to migration of worms to other sites. Many cases are managed surgically, usually for suspected appendicitis. Biopsy of inflamed intestinal tissue may show worms localized to mesenteric arteries and eosinophilic granulomas. It is not known if antihelminthic therapy is helpful, but diethylcarbamazine, thiabendazole, and mebendazole have been used.

Wang QP et al. Human angiostrongyliasis. Lancet Infect Dis. 2008 Oct;8(10):621–30. [PMID: 18922484]

Gnathostomiasis

A number of species of *Gnathostoma*, which are parasites of carnivores, can occasionally infect humans. Most cases have been seen in Southeast Asia, but the disease has also been described in many other areas. Eggs shed in the feces of mammals are ingested by marine crustaceans, which are then ingested by fish, frogs, snakes, or mammals. Larvae then encyst in muscles. Human infection follows eating undercooked fish, shellfish, chicken, or pork and can also be transmitted by ingesting copepods in contaminated water. After ingestion, larvae cannot complete development in humans, but rather migrate through tissues (see illustration).

Fig.

Life cycle of *Gnathostoma spinigerum*. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Acute gastrointestinal symptoms, including nausea, vomiting, abdominal pain, and fever, may develop soon after infection and persist for 2–3 weeks. The disease may then progress to findings consistent with cutaneous or visceral larva migrans. Migratory subcutaneous erythematous swellings may be painful or pruritic. Migrating larvae may also invade other tissues, leading to findings in the eyes, lungs, intestines, and elsewhere (see photograph). The most serious complications are due to invasion of the CNS, leading to eosinophilic meningoencephalitis and other serious findings. Although a less common cause of eosinophilic meningitis than *A cantonensis* infection, gnathostomiasis tends to be more severe. Severe pain due to migration through spinal roots and focal neurologic findings may be seen. Symptoms are highly variable over time. CSF eosinophilic pleocytosis and peripheral eosinophilia are seen.

Fig.

Gnathostomiasis of the right eyelid. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

The diagnosis of gnathostomiasis is suggested by the history of intermittent subcutaneous swellings and typical CNS findings. Worms can occasionally be identified in skin lesions. Serologic tests may be helpful in establishing a diagnosis. Treatment is with ivermectin (200 mcg/kg orally single dose) or albendazole (400 mg/kg orally daily for 21 days); both treatments have reported cure rates over 90%.

for the treatment of gnathostomiasis. Southeast Asian J Trop Med Public Health. 2005 May;36(3):650–2. [PMID: 16124432]

Toxocariasis

General Considerations

The dog roundworm *Toxocara canis,* the cat roundworm *Toxocara cati,* and less commonly other helminths may cause visceral larva migrans. *T canis* is highly prevalent in dogs. Humans are infected after ingestion of eggs in material contaminated by dog or other feces. With *T canis*, infection is spread principally by puppies and lactating females, and the eggs must be on the ground for several weeks before they are infectious. After ingestion by humans, larvae migrate to various tissues but cannot complete their life cycle.

Clinical Findings

Visceral larva migrans is seen principally in young children. Most infections are asymptomatic. The most commonly involved organs are the liver and lungs. Presentations include cough, fever, wheezing, hepatomegaly, splenomegaly, lymphadenopathy, pulmonary infiltrates, and eosinophilia. Involvement of the CNS can occur rarely, leading to eosinophilic meningitis and other abnormalities. Ocular larva migrans is a distinct syndrome, usually in children older than is typical for visceral larva migrans. Children present with visual deficits, pain, and a retinal mass, which can be confused with retinoblastoma. *Baylisascaris procyonis,* a roundworm of raccoons, can rarely cause visceral larva migrans in humans, with typically more severe manifestations than those with *T canis,* including eosinophilic meningitis and eye disease.

The diagnosis of visceral larva migrans is suggested by the finding of eosinophilia in a child with hepatomegaly or other signs of the disease, especially with a history of exposure to puppies. The diagnosis is confirmed by the identification of larvae in a biopsy of infected tissue, usually performed when other diseases are suspected. Serologic tests may be helpful; an available ELISA was estimated to have 78% sensitivity and 92% specificity. Most patients recover without specific therapy, although symptoms may persist for months.

Treatment

Treatment with antihelminthics or corticosteroids may be considered in severe cases. No drugs have been proven to be effective, but albendazole (400 mg twice daily for 5 days), mebendazole, thiabendazole, diethylcarbamazine, and ivermectin have been used, and albendazole has been recommended as the treatment of choice.

Cutaneous Larva Migrans (Creeping Eruption)

Cutaneous larva migrans is caused principally by larvae of the dog and cat hookworms, *Ancylostoma braziliense* and *A caninum.* Other animal hookworms, gnathostomiasis, and strongyloidiasis may also cause this syndrome. Infections are common in warm areas, including the southeastern United States. They are most common in children. The disease is caused by the migration of worms through skin; the non-human parasites cannot complete their life cycles, so only cause cutaneous disease.

Clinical Findings

Intensely pruritic erythematous papules develop, usually on the feet or hands, followed within a few days by serpiginous tracks marking the course of the parasite, which may travel several millimeters per day (Plate 118). Several tracks may be present (see photograph); (see photograph). The process may continue for weeks, with lesions becoming vesiculated, encrusted, or secondarily infected. Systemic symptoms or eosinophilia are uncommon.

Fig.

Cutaneous larva migrans. Note track from the mouth of a child who had ingested dirt containing cat hookworm filariform larvae. (Courtesy of H Zaiman.)

The diagnosis is based on the characteristic appearance of the lesions. Biopsy is usually not indicated.

Treatment

Without treatment, the larvae eventually die and are absorbed. Mild cases do not require treatment. Thiabendazole (10% aqueous suspension) can be applied topically three times daily for 5 or more days. Systemic therapy with albendazole (400 mg orally once or twice daily for 3–5 days) or ivermectin (200 mcg/kg orally single dose) is highly effective.

[PMID: 18471775]

Anisakiasis

Anisakiasis is caused by infection with larvae of saltwater fish and squid. Multiple species of the family *Anisakidae* may occasionally infect humans. Definitive hosts for these parasites are marine mammals. Eggs are passed in the feces and ingested by crustaceans, which are then eaten by fish and squid. When ingested by humans in undercooked seafood, larvae penetrate the stomach or intestinal wall but cannot complete their life cycle. The disease is most common in Japan.

Clinical Findings

Clinical manifestations of anisakiasis follow burrowing of worms into the stomach or intestinal wall, leading to localized ulceration, edema, and eosinophilic granuloma formation (see micrograph). Symptoms usually occur within 2 days of parasite ingestion and include severe epigastric or abdominal pain, nausea, and vomiting. Intestinal involvement can mimic appendicitis. Allergic symptoms, including urticaria, angioedema, and anaphylaxis, have also been attributed to acute infection. Acute symptoms generally resolve within 2 weeks, but chronic symptoms may also be seen, suggesting chronic intestinal diseases such as inflammatory bowel disease, diverticulitis, or carcinoma. Rarely, worms may migrate to other sites or be coughed up. Eosinophilia is usually not seen.

Fig.

Cross section of an anisakid larva in human granuloma. (Courtesy of N Kagei.)

The diagnosis of anisakiasis is suggested in those with acute abdominal symptoms after ingestion of raw fish. Radiographic studies may identify stomach or intestinal lesions, and endoscopy may allow visualization and removal of the worm (see endoscopy). When surgery is performed due to consideration of other diagnoses, eosinophilic inflammatory lesions and the invading worms are found.

Fig.

Live anisakid larva observed by gastroscopy. (Courtesy of N Kagei.)

Treatment

Specific therapy is not indicated, but endoscopic worm removal hastens recovery. The parasites are killed by cooking or deep freezing fish.

Lymphatic Filariasis

Essentials of Diagnosis

- Episodic attacks of lymphangitis, lymphadenitis, and fever.
- Chronic progressive swelling of extremities and genitals; hydrocele; chyluria; lymphedema.
- Microfilariae in blood, chyluria, or hydrocele fluid; positive serologic tests.

Lymphatic filariasis is caused by three filarial nematodes: *Wuchereria bancrofti*, *Brugia malayi*, and *Brugia timori*, and is among the most important parasitic diseases of man. Approximately 120 million people are infected with these organisms in tropical and subtropical countries, about a third of these suffer clinical consequences of the infections, and many are seriously disfigured. *W bancrofti* causes about 90% of episodes of lymphatic filariasis. It is transmitted by *Culex, Aedes,* and *Anopheles* mosquitoes and is widely distributed in the tropics and subtropics, including subsaharan Africa, Southeast Asia, the western Pacific, India, South America, and the Caribbean. *B malayi* is transmitted by *Mansonia* and *Anopheles* mosquitoes and is endemic in parts of China, India, Southeast Asia, and the Pacific. *B timori* is found only in islands of southeastern Indonesia (see illustration).

Fig.

Filariasis (elephantiasis). Life cycles of *Wuchereria bancrofti* and *Brugia malayi* . A person is bitten by an infected mosquito while asleep. Larvae leave the mouth parts and penetrate through the bite or via a hair follicle. ***1–3:*** Developing worms localize in lymph nodes, mature after 1 year, mate, and produce sheathed microfilariae (1), which circulate in the bloodstream (2), from which they are withdrawn by another mosquito. The larvae develop in the thoracic musculature of the vector (3). The infective larvae collect in the mosquito's proboscis for transport and transmission to another human host. The pathologic process after chronic infection is associated with lymph stasis, fibrosis, and development of collateral circulation, with continued tissue growth and, ultimately, massive growth and enlargement associated with a host sensitization reaction. Note that when elephantiasis develops, the filariae have usually been killed; transmission of microfilariae to a mosquito is therefore from the unaffected leg. It is likely, however, that such transmission would occur only prior to development of elephantiasis. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Humans are infected by the bites of infected mosquitoes. Larvae then move to the lymphatics and lymph nodes, where they mature over months to thread-like adult worms, and then can persist for many years. The adult worms produce large numbers of microfilariae, which are released into the circulation, and infective to mosquitoes, particularly at night (except for the South Pacific, where microfilaremia peaks during daylight hours).

Clinical Findings

Symptoms and Signs

Many infections remain asymptomatic despite circulating microfilariae. Clinical consequences of filarial infection are principally due to inflammatory responses to developing, mature, and dying worms. The initial manifestation of infection is often acute lymphangitis, with fever, painful lymph nodes, edema, and inflammation spreading peripherally from involved lymph nodes (in contrast to bacterial lymphangitis, which spreads centrally). Lymphangitis and lymphadenitis of the upper and lower extremities is common (Plate 119); genital involvement, including epididymitis and orchitis, with scrotal pain and tenderness, occurs principally only with *W bancrofti* infection. Acute attacks of lymphangitis last for a few days to a week and may recur a few times per year. Filarial fevers may also occur without lymphatic inflammation.

Plate 119

Elephantiasis of legs due to filariasis. (Public Health Image Library, CDC.)

The most common chronic manifestation of lymphatic filariasis is swelling of the extremities or genitals due to chronic lymphatic inflammation and obstruction. Extremities become increasingly swollen, with a progression over time from pitting edema, to nonpitting edema, to sclerotic changes of the skin that are referred to as elephantiasis. Genital involvement, particularly with *W bancrofti,* occurs more commonly in men, progressing from painful epididymitis to hydroceles that are usually painless but can become very large, with inguinal lymphadenopathy, thickening of the spermatic cord, scrotal lymphedema, thickening and fissuring of the scrotal skin, and occasionally chyluria. Lymphedema of the female genitalia and breasts may also occur.

Tropical pulmonary eosinophilia is a distinct syndrome principally affecting young adult males with either *W bancrofti* or *B malayi* infection but typically without microfilaremia. This syndrome is characterized by asthma-like symptoms, with cough, wheezing, dyspnea, and low-grade fevers, usually at night. Without treatment, tropical pulmonary eosinophilia can progress to interstitial fibrosis and chronic restrictive lung disease.

Laboratory Findings

The diagnosis of lymphatic filariasis is strongly suggested by characteristic findings of lymphangitis or lymphatic obstruction in persons with risk factors for the disease. The diagnosis is confirmed by finding microfilariae, usually in blood, but this may be difficult (see illustration). In addition, microfilariae may be absent, especially early in the disease progression (first 2–3 years) or with chronic obstructive disease. To increase yields, blood samples are obtained at about midnight in most areas, but not in the South Pacific, where microfilaremia is diurnal. Smears are evaluated by wet mount to identify motile parasites and by Giemsa staining; these examinations can be delayed until the following morning, with storage of samples at room temperature. Of note, the periodicity of microfilaremia is variable, and daytime samples may yield positive results. Microfilariae may also be identified in hydrocele fluid or chylous urine. Eosinophilia is usually absent, except during acute inflammatory syndromes. Available serologic tests, including bentonite flocculation, indirect hemagglutination, ELISA, and indirect fluorescent antibody tests, may be helpful but cannot distinguish between past and active infections. Rapid antigen tests with sensitivity and specificity over 90% are available. Adult worms may also be found in lymph node biopsy specimens (although biopsy is not usually clinically indicated) or by ultrasound of a scrotal hydrocele or lymphedematous breast. When microfilaremia is lacking, especially if sophisticated techniques are not available, diagnoses may need to be made on clinical grounds alone.

Treatment & Control

Drug Treatment

Treatment is somewhat controversial, as no drug can fully control or reverse the disease, and treatment may cause serious acute inflammatory symptoms. Diethylcarbamazine is the drug of choice, but it cannot cure infections due to its limited action against adult worms. Asymptomatic infection and acute lymphangitis are treated with this drug (2 mg/kg orally three times daily) for 10–14 days, leading to a marked decrease in microfilaremia. Therapy may be accompanied by allergic symptoms, including fever, headache, malaise, hypotension, and bronchospasm, probably due to release of antigens from dying worms. For this reason, treatment courses may begin with a lower dosage, with escalation over the first 4 days of treatment. Single annual doses of diethylcarbamazine (6 mg/kg orally), alone or with ivermectin (400 mcg/kg orally) or albendazole (400 mg orally) may be as effective as longer courses of diethylcarbamazine. When onchocerciasis or loiasis is suspected, it may be appropriate to withhold diethylcarbamazine to avoid severe reactions to dying microfilariae; rather, ivermectin plus albendazole may be given, although these drugs are less active than diethylcarbamazine against adult worms. Appropriate management of advanced obstructive disease is uncertain. Drainage of hydroceles provides symptomatic relief, although they will recur. Therapy with diethylcarbamazine cannot reverse chronic lymphatic changes but is typically provided to lower worm burdens. An interesting approach under study is to treat with doxycycline (100–200 mg/d orally for 4–6 weeks), which kills obligate intracellular *Wolbachia* bacteria, leading to death of adult filarial worms. Secondary bacterial infections must be treated. Surgical correction may be helpful in some cases.

Disease Control

Avoidance of mosquitoes is a key measure; preventive measures include the use of screens, bed nets (ideally treated with insecticide), and insect repellents. Community-based treatment with single annual doses of effective drugs offers a highly effective means of control. The current WHO strategy for control includes mass treatment of at risk communities with single annual doses of diethylcarbamazine plus albendazole or, for areas with onchocerciasis, albendazole plus ivermectin.

Dis. 2005 Aug;5(8):514–23. [PMID: 16048720]

Onchocerciasis

Essentials of Diagnosis

- Severe pruritus, skin excoriations, pigment changes, nodules, and thickening.
- Conjunctivitis progressing to severe eye disease and blindness.
- Microfilariae in skin snips and on slit-lamp examination; adult worms in subcutaneous nodules.

General Considerations

Onchocerciasis, or river blindness is caused by *Onchocerca volvulus.* An estimated 18 million persons are infected, of whom 3–4 million have skin disease, 500,000 have severe visual impairment, and 300,000 are blinded. Over 99% of infections are in subsaharan Africa, especially the West African savanna, with about half of cases in Nigeria and Congo. In some hyperendemic African villages, close to 100% of individuals are infected, and 10% or more of the population is blind. The disease is also prevalent in the southwestern Arabian peninsula and Latin America, including southern Mexico, Guatemala, Venezuela, Colombia, Ecuador, and northwestern Brazil. Onchocerciasis is transmitted by simulium flies (blackflies). These insects breed in fast-flowing streams and bite during the day.

After the bite of an infected blackfly, larvae are deposited in the skin, where adults develop over 6–12 months. Adult worms live in subcutaneous connective tissue or muscle nodules for a decade or more. Microfilariae are released from the nodules and migrate through subcutaneous and ocular tissues. Disease is due to responses to worms and to intracellular *Wolbachia* bacteria (see illustration).

Fig.

Life cycle of *Onchocerca volvulus* (blinding worm). Numerous blackflies (*Simulium*) swarm and bite near a breeding site in a fast-moving stream in Africa or Central America. Adult onchocercae develop in a dermal nodule in a tangle of several worms. At bottom, unsheathed microfilariae migrate in the interstitial fluid of the dermis, inducing skin changes through a loss of elasticity and other effects, causing "hanging groin" and scaly, thickened, or depigmented areas, especially in the legs. A blackfly takes up microfilariae while feeding on blood and tissue fluids. At left are shown pupae and larvae of *Simulium* on aquatic vegetation. Damage to the eye from chronic infection leads to collection of many microfilariae in the eye, ultimately causing blindness. (Reproduced, with permission, from Goldsmith R,

Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Clinical Findings

Symptoms and Signs

After an incubation period of up to 1–3 years, the disease typically produces an erythematous, papular, pruritic rash, which may progress to chronic skin thickening and depigmentation (see photograph). Itching may be severe and unresponsive to medications, such that more disability-adjusted life years are lost to onchocercal skin problems than to blindness (see photograph); (see photograph); (see photograph). Numerous firm, nontender, movable subcutaneous nodules of about 0.5–3 cm, which contain adult worms, may be present. Due to differences in vector habits, these nodules are more commonly on the lower body in Africa but on the head and upper body in Latin America. Inguinal and femoral lymphadenopathy is common, at times resulting in a "hanging groin," with lymph nodes hanging within a sling of atrophic skin. Patients may also have systemic symptoms, with weight loss and musculoskeletal pain.

Fig.

Snowflake opacities seen by slitlamp examination in late-stage ophthalmic onchocerciasis. (Courtesy of W Peters and HM Gilles.)

The most serious manifestations of onchocerciasis involve the eyes. Microfilariae migrating through the eyes elicit host responses that lead to pathology. Findings include punctate keratitis and corneal opacities, progressing to sclerosing keratitis and blindness. Iridocyclitis, glaucoma, choroiditis, and optic atrophy may also lead to vision loss. The likelihood of blindness after infection varies greatly based on geography, with the risk greatest in savanna regions of West Africa.

Diagnostic Testing

The diagnosis is made by identifying microfilariae in skin snips, by visualizing microfilariae in the cornea or anterior chamber by slit-lamp examination, by identification of adult worms in a biopsy or aspirate of a nodule or, uncommonly, by identification of microfilariae in urine. Skin snips from the iliac crest (Africa) or scapula (Americas) are allowed to stand in saline for 2–4 hours or longer, and then examined microscopically for microfilariae. Deep punch biopsies are not needed, and if suspicion persists after a skin snip is negative, the procedure should be repeated. Ultrasound may identify characteristic findings suggestive of adult worms in skin nodules. When the diagnosis remains difficult, the

Mazzoti test can be used. In this test, a 50-mg dose of diethylcarbamazine is given. A positive test, with exacerbation of skin rash and pruritus, usually within 3 hours, is highly suggestive of the diagnosis. This test should only be used in suspected lightly infected patients (after other tests are negative), as this treatment can elicit severe skin and eye reactions in heavily infected individuals. A related and safer test using topical diethylcarbamazine is available in some areas. Eosinophilia is a common, but inconsistent finding. Serologic tests are poorly standardized, nonspecific, and generally unhelpful, as in endemic areas positivity is not indicative of acute disease.

Treatment & Control

The treatment of choice is ivermectin, which has replaced diethylcarbamazine due to a much lower risk of severe reactions to therapy. Ivermectin kills microfilariae, but not adult worms, so disease control requires repeat administrations. Treatment is with a single oral dose of 150 mcg/mL, but schedules for re-treatment have not been standardized. One regimen is to treat every 3 months for 1 year, followed by treatment every 6–12 months for the suspected lifespan of adult worms (about 15 years). Treatment results in marked reduction in numbers of microfilariae in the skin and eyes, although its impact on the progression of visual loss remains uncertain.

Toxicities of ivermectin are generally mild; fever, pruritus, urticaria, myalgias, edema, hypotension, and tender lymphadenopathy may be seen, presumably due to reactions to dying worms. Ivermectin should be used with caution in patients also at risk for loiasis, since it can elicit severe reactions including encephalopathy. In patients with severe skin findings not controlled by ivermectin, therapy with suramin may be considered. This is the only drug known to kill adult worms, but it is very toxic. As with other filarial infections, doxycycline acts against *O volvulus* by killing intracellular *Wolbachia* bacteria. A course of 100 mg/day for 6 weeks kills the bacteria and prevents parasite embryogenesis for at least 18 months. Doxycycline is under study for onchocerciasis control but has no clear role in treatment of individual affected patients.

Protection against onchocerciasis includes avoidance of biting flies. Major efforts are underway to control insect vectors in Africa. In addition, mass distribution of ivermectin for intermittent administration at the community level is ongoing, and the prevalence of severe skin and eye disease is decreasing.

Loiasis

Essentials of Diagnosis

- Subcutaneous swellings; adult worms migrating across the eye.
- Encephalitis, which may be brought on by treatment.
- Microfilariae in the blood.

General Considerations

Loiasis is a chronic filarial disease caused by infection with *Loa loa*. The infection occurs in humans and monkeys in rainforest areas of West and central Africa. An estimated 3–13 million persons are infected. The disease is transmitted by chrysops flies, which bite during the day. Over 6–12 months after infection, larvae develop into adult worms, which migrate through subcutaneous tissues, including the subconjunctiva (leading to the term "eye worm"). Adults can live for up to 17 years (see illustration).

Fig.

Life cycle of *Loa loa*. A West African woman is shown being bitten by a day-biting mango fly (*Chrysops*). Infective *L loa* deposited on the skin penetrates a follicle and develops in subcutaneous tissues, where it wanders as an adult, occasionally passing over the eye. Sheathed microfilariae in the bloodstream (lower right) are taken up by a vector. The local reaction to the worm or its products is typically a fugitive swelling (Calabar swelling) near a thin area of flesh over bone (eg, a hand), rarely in soft tissues (eg, the face). (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Clinical Findings

Symptoms and Signs

Many infected persons are asymptomatic, although they may have high levels of microfilaremia and eosinophilia. Transient subcutaneous swellings (Calabar swellings) develop in symptomatic persons. The swellings are nonerythematous, up to 20 cm in diameter, and may be preceded by local pain or pruritus. They usually resolve after 2–4 days but occasionally persist for several weeks. Calabar swellings are commonly seen around joints and may recur at the same or different sites. Visitors from nonendemic areas are more likely to have allergic-type reactions, including pruritus, urticaria, and angioedema. Adult worms may be seen to migrate across the eye, with either no symptoms or conjunctivitis, with pain and edema. The most serious complication of loiasis is encephalitis, which is most common in those with high level microfilaremia and microfilariae in the CSF. Symptoms may range from headache and insomnia to coma and death. Encephalitis may be brought on by treatment with diethylcarbamazine or ivermectin. Other complications of loiasis include kidney disease, with hematuria and proteinuria; endomyocardial fibrosis; and peripheral neuropathy.

Laboratory Findings

The diagnosis is established by identifying microfilariae in blood (see illustration). Blood is evaluated as for lymphatic filariasis, but for loiasis blood should be obtained during the day. The failure to find microfilariae does not rule out the diagnosis. Identification of a migrating eye worm is also diagnostic. Serologic tests may be helpful in persons from nonendemic areas who may be acutely ill without detectable microfilaremia, but such tests have limited utility for residents of endemic areas because most of them will have positive test results. Diagnostic PCR methods have been described.

Fig.

Microfilariae in tissue fluids: *Loa loa*. (Reproduced, with permission, from Goldsmith R, Heyneman D [editors]: *Tropical Medicine and Parasitology*. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Treatment

The treatment of choice is diethylcarbamazine, which eliminates microfilariae and has some activity against adult worms. Treatment with 8–10 mg/kg/d orally for 21 days is curative in about 50% of amicrofilaremic patients, and repeat courses increase efficacy. Mild side effects are common with therapy, including fever, pruritus, arthralgias, nausea, diarrhea, and Calabar swellings. These symptoms may be lessened by administration of antihistamines or corticosteroids. Patients with large worm burdens are at greater risk for serious complications of therapy, including kidney injury, shock, encephalitis, coma, and death. Treatment with ivermectin, which is highly active against microfilariae, but not adult worms, also entails a high risk of severe reactions. To attempt to avoid these sequelae, pretreatment with corticosteroids and antihistamines, and escalating dosage of diethylcarbamazine have been used, but this strategy does not prevent encephalitis. The circulating parasite load that indicates particular risk for severe complications with therapy has been estimated at 2500/mL or greater. Strategies to treat patients with high parasite loads include (1) no treatment; (2) apheresis, if available, to remove microfilariae prior to therapy with diethylcarbamazine; or (3) therapy with albendazole, which appears to be well tolerated due to its slow antiparasitic effects, prior to therapy with diethylcarbamazine or ivermectin.

Fungal Infections: Introduction

Fungal infections have assumed an increasingly important role as use of broad-spectrum antimicrobial agents has increased and the number of immunodeficient patients has risen. Some pathogens (eg, *Cryptococcus*, *Candida*, *Pneumocystis*, *Fusarium*) rarely cause serious disease in normal hosts. Other endemic fungi (eg, histoplasma, coccidioides, paracoccidioides) commonly cause disease in normal hosts but tend to be more aggressive in immunocompromised ones. Superficial mycoses are discussed in Chapter 6: Dermatologic Disorders.

Successful management of most systemic fungal infections requires knowledge of the natural history of these diseases as well as familiarity with the unique pharmacokinetics, adverse effects, and drug interactions of the various therapeutic agents. Furthermore, most affected individuals usually have significant underlying illnesses. Consequently, clinicians with extensive experience in the management of these disorders should be consulted.

Candidiasis

Essentials of Diagnosis

- Common normal flora but opportunistic pathogen.
- Gastrointestinal mucosal disease, particularly esophagitis, most common.
- Catheter-associated fungemia occurs in patients who have sustained mucosal injury or received broad-spectrum antibiotics.

General Considerations

Candida albicans can be cultured from the mouth, vagina, and feces of most people. Cutaneous and oral lesions are discussed in Chapter 6: Dermatologic Disorders and Chapter 8: Ear, Nose, & Throat Disorders, respectively. The risk factors for invasive candidiasis include prolonged neutropenia, recent abdominal surgery, broad-spectrum antibiotic therapy, advanced chronic kidney disease, the presence of intravascular catheters (especially when providing total parenteral nutrition), and injection drug use. Cellular immunodeficiency predisposes to mucocutaneous disease. When no other underlying cause is found, persistent oral or vaginal candidiasis should arouse a suspicion of HIV infection.

Clinical Findings & Treatment

Mucosal Candidiasis

Esophageal involvement is the most frequent type of significant mucosal disease. Presenting symptoms include substernal odynophagia, gastroesophageal reflux, or nausea without substernal pain. Oral candidiasis, though often associated, is not invariably present. Diagnosis is best confirmed by endoscopy with biopsy and culture. Therapy depends on the severity of disease. If patients are able to swallow and take adequate amounts of fluid orally, fluconazole, 100 mg/d (or itraconazole solution, 10 mg/mL, 200 mg/d), for 10–14 days will usually suffice. In the individual who is more ill or in whom esophagitis has developed while taking fluconazole, options include oral or intravenous voriconazole, 200 mg twice daily; intravenous amphotericin B, 0.3 mg/kg/d; intravenous caspofungin, 50 mg/d; intravenous anidulafungin, 100 mg on day 1, then 50 mg/d; or intravenous micafungin, 150 mg/d. Relapse is common with all agents when there is underlying HIV infection without adequate immune reconstitution.

Vulvovaginal candidiasis occurs in an estimated 75% of women during their lifetime. Risk factors include pregnancy, uncontrolled diabetes mellitus, broad-spectrum antimicrobial treatment, corticosteroid use, and HIV infection. Symptoms include acute vulvar pruritus, burning vaginal discharge, and dyspareunia. Various topical azole preparations (eg, clotrimazole, 100 mg vaginal tablet for 7 days, or miconazole, 200 mg vaginal suppository for 3 days) are effective. One 150 mg oral dose of fluconazole has been shown to have equivalent efficacy with better patient acceptance. Disease recurrence is common but can be decreased with weekly fluconazole therapy (150 mg weekly).

Candidal Funguria

Candidal funguria frequently resolves with discontinuance of antibiotics or removal of bladder catheters. Clinical benefit from treatment of asymptomatic candiduria has not been demonstrated, but persistent funguria should raise the suspicion of disseminated infection. When symptomatic funguria persists, oral fluconazole, 200 mg/d for 7–14 days, can be used. Rare complications of candidal urinary tract infections are ureteral obstruction and dissemination.

Disseminated Candidiasis

The diagnosis of disseminated *Candida* infection is problematic because *Candida* species are often isolated from mucosal sites in the absence of invasive disease while blood cultures are positive only 50% of the time in disseminated infection. Serologic tests have not proved useful for distinguishing colonization from invasive disease. Thus, the decision to treat for *Candida* when organisms are isolated from urine or sputum (or both) needs to be individualized for each patient. A randomized trial of empiric fluconazole for patients at high risk for, but not proven to have, disseminated candidiasis showed no clinical benefit compared with placebo. Disseminated candidiasis may represent a benign, self-limited process, but until proven otherwise it should be considered a sign of serious, complicated disease.

Organ system involvement in invasive disease may include the eyes, skin, brain, meninges, and myocardium. Antifungal therapy for invasive candidiasis is rapidly evolving with the addition of new agents and the emergence of non-*albicans* species causing significant disease. Options for treatment include fluconazole, 400–800 mg daily; amphotericin B, 0.7 mg/kg/d; liposomal amphotericin B, 3 mg/kg/d; voriconazole, 200 mg twice a day; caspofungin, 50 mg/d; micafungin, 100 mg daily; or anidulafungin, 100 mg/d after 200 mg intravenously once.

Therapy for disseminated candidiasis should be continued for 2 weeks after the last positive blood culture and resolution of symptoms and signs of infection. Once patients have become clinically stable, parenteral therapy can be discontinued and oral fluconazole, 200–800 mg orally given as one or two doses daily, is used to complete treatment. Removal or exchange of intravascular catheters is generally recommended and substantially decreases the duration of candidemia and overall mortality, which approaches 30%.

Another form of invasive disease is hepatosplenic candidiasis. This results from aggressive chemotherapy and prolonged neutropenia in patients with underlying hematologic cancers. Typically, fever and variable abdominal pain present weeks after chemotherapy, when neutrophil counts have recovered. Blood cultures are generally negative. Hepatic enzymes reveal an alkaline phosphatase elevation that may be marked. Fluconazole, 400 mg daily, or a lipid formulation of amphotericin B should be given until clinical and radiographic improvement occurs.

Candidal Endocarditis

Candidal endocarditis rarely is a complication of transient fungemia. It usually results from direct inoculation at the time of valvular heart surgery or repeated inoculation with injection drug use. Candidal endocarditis occurs with increased frequency on prosthetic valves in the first few months following surgery. Splenomegaly and petechiae are common, and there is a predilection for large-vessel embolization. The diagnosis is established definitively by culturing *Candida* from emboli or from vegetations at the time of valve replacement. Valve destruction (usually aortic or mitral), myocardial ring abscess, and systemic embolization are common. Amphotericin has long been considered the optimal therapy, given in a dosage of 0.5–1 mg/kg/d intravenously, although there are now more and more data regarding the utility of echinocandin and imidazole.

Non-*albicans* species of *Candida* now account for over 50% of clinical bloodstream isolates and are often resistant to imidazole antibiotics such as fluconazole. The widespread use of these agents for prophylaxis in immunocompromised patients can lead to the emergence of pathogens such as *Candida krusei.* Azole-resistant *C albicans* has increased in frequency in immunocompromised patients, particularly in patients with late-stage AIDS receiving long-term suppressive fluconazole.

In all forms of invasive candidiasis, an important element of therapy is reversal of the underlying predisposing factor when possible. In high-risk patients undergoing induction chemotherapy, bone marrow transplantation, or liver transplantation, prophylaxis with antifungal agents has been shown to prevent invasive fungal infections although the effect on mortality and the preferred agent remain debated.

Histoplasmosis

Essentials of Diagnosis

- Epidemiologically linked to bird droppings and bat exposure; common along river valleys (especially the Ohio River and the Mississippi River valleys).
- Most patients asymptomatic; respiratory illness most common clinical problem.

- Widespread disease especially common in AIDS or other immunosuppressed states, with poor prognosis.
- Biopsy of affected organs with culture or urinary polysaccharide antigen most useful in disseminated disease.

General Considerations

Histoplasmosis is caused by *Histoplasma capsulatum*, a dimorphic fungus that has been isolated from soil contaminated with bird or bat droppings in endemic areas (central and eastern United States, eastern Canada, Mexico, Central America, South America, Africa, and southeast Asia). Infection presumably takes place by inhalation of conidia. These convert into small budding cells that are engulfed by phagocytes in the lungs. The organism proliferates and is carried hematogenously to other organs.

Clinical Findings

Symptoms and Signs

Most cases of histoplasmosis are asymptomatic or mild and thus go unrecognized. Past infection is recognized by pulmonary and splenic calcification noted on incidental radiographs. Symptoms and signs of pulmonary involvement are usually absent even in patients who subsequently show areas of calcification on chest radiographs. Symptomatic infection may present with mild influenza-like illness, often lasting 1–4 days. Moderately severe infections are frequently diagnosed as atypical pneumonia. These patients have fever, cough, and mild central chest pain lasting 5–15 days.

Clinically evident infections occur in several forms: (1) **Acute histoplasmosis** frequently occurs in epidemics, often when soil containing infected bird or bat droppings is disturbed. It is a severe disease manifested by marked prostration, fever, and relatively few pulmonary complaints even when radiographs show diffuse pneumonia. The illness may last from 1 week to 6 months but is almost never fatal. (2) **Progressive disseminated histoplasmosis** is usually fatal within 6 weeks or less. Symptoms usually consist of fever, dyspnea, cough, loss of weight, and prostration. Ulcers of the mucous membranes of the oropharynx may be present. The liver and spleen are nearly always enlarged, and all the organs of the body are involved, particularly the adrenal glands, though this infrequently results in adrenal insufficiency. Gastrointestinal involvement may mimic inflammatory bowel disease. (3) **Chronic progressive pulmonary histoplasmosis** is usually seen in older patients with various lesions including apical cavities, infiltrates, and nodules found on radiographs. (4) **Disseminated disease** usually occurs in the profoundly immunocompromised person but can affect immunocompetent persons as well. This form is commonly seen in patients with underlying

HIV infection—with CD4 cell counts usually < 100 cells/mcL—and is characterized by fever and multiple organ system involvement. Chest radiographs may show a miliary pattern. Presentation may be fulminant, simulating septic shock, with death ensuing rapidly unless treatment is provided.

Laboratory Findings

Most patients with progressive pulmonary disease show anemia of chronic disease. Bone marrow involvement may be prominent in disseminated forms with occurrence of pancytopenia. Alkaline phosphatase and marked lactate dehydrogenase (LDH) and ferritin elevations are also common as are mild elevations of serum aspartate aminotransferase, although alanine aminotransferase is often normal.

In pulmonary disease, sputum culture is rarely positive except in chronic disease; antigen testing of bronchoalveolar lavage fluid may be helpful in acute disease. Blood or bone marrow cultures from immunocompromised patients with acute disseminated disease are positive more than 80% of the time but may take several weeks. A urine antigen assay has a sensitivity of greater than 90% for disseminated disease in AIDS patients and can be used to follow response to therapy. The sensitivity of screening immunodiffusion is 70% in acute pulmonary histoplasmosis, and complement fixation titers are positive in about 80% of cases. Patients with disseminated histoplasmosis may have a false-positive *Aspergillus* galactomannan assay.

Treatment

For progressive localized disease and for mild to moderately severe nonmeningeal disseminated disease in immunocompetent or immunocompromised patients, itraconazole, 200–400 mg/d orally divided into two doses, is the treatment of choice with an overall response rate of approximately 80%. The oral solution is better absorbed than the capsule formulation. Duration of therapy ranges from weeks to several months depending on the severity of illness. Amphotericin B is reserved for individuals who cannot take oral medications; for those who have not responded to itraconazole therapy; for those with meningitis; and for management of severe disseminated disease in an immunocompromised person. Up to 2.5 g total may need to be given in the latter two situations, though this course of treatment can be abbreviated and oral itraconazole instituted once clinical stabilization has occurred. Liposomal amphotericin B in a dosage of 3 mg/kg/d intravenously may be more effective and safer than conventional amphotericin B in seriously ill individuals. Patients with AIDS-related histoplasmosis require lifelong suppressive therapy with itraconazole, 200–400 mg/d orally, although secondary prophylaxis may be discontinued if immune reconstitution occurs in response to antiretroviral therapy.

Coccidioidomycosis

Essentials of Diagnosis

- Influenza-like illness with malaise, fever, backache, headache, and cough.
- Erythema nodosum common with acute infection.
- Dissemination may result in meningitis, bony lesions, or skin and soft tissue abscesses.
- Chest radiograph findings vary widely from pneumonitis to cavitation.
- Serologic tests useful; spherules containing endospores demonstrable in sputum or tissues.

General Considerations

Coccidioidomycosis should be considered in the diagnosis of any obscure illness in a patient who has lived in or visited an endemic area.

Infection results from the inhalation of arthroconidia of *Coccidioides immitis* or *Coccidioides posadasii;* both organisms are molds that grow in soil in certain arid regions of the southwestern United States, in Mexico, and in Central and South America.

Less than 1% of immunocompetent persons show dissemination, but among these patients the mortality rate is high.

In HIV-infected people in endemic areas, coccidioidomycosis is a common opportunistic infection. In these patients, disease manifestations range from focal pulmonary infiltrates to widespread miliary disease with multiple organ involvement and meningitis.

Clinical Findings

Symptoms and Signs

Symptoms of primary coccidioidomycosis occur in about 40% of infections. Symptom onset (after an incubation period of 10–30 days) is usually that of a respiratory tract illness with fever and occasionally chills, and coccidioidomycosis is a common etiology of community-acquired pneumonia in endemic areas.

Arthralgia accompanied by periarticular swelling, often of the knees and ankles, is common. Erythema nodosum may appear 2–20 days after onset of symptoms. Persistent pulmonary lesions, varying from cavities and abscesses to parenchymal nodular densities or bronchiectasis, occur in about 5% of diagnosed cases.

Disseminated disease occurs in about 0.1% of white and 1% of nonwhite patients. Filipinos and blacks are especially susceptible, as are pregnant women of all races. Any organ may be involved. Pulmonary findings usually become more pronounced, with mediastinal lymph node enlargement, cough, and increased sputum production. Lung abscesses may rupture into the pleural space, producing an empyema. These may also extend to bones and skin, and pericardial and myocardial involvement has been occasionally observed. Fungemia may occur and is characterized clinically by a diffuse miliary pattern on chest radiograph and by early death. The course may be particularly rapid in immunosuppressed patients. Physicians caring for immunosuppressed patients in endemic areas need to consider that patients may be latently infected.

Bone lesions most often occur at bony prominences. Meningitis occurs in 30–50% of cases of dissemination. Subcutaneous abscesses and verrucous skin lesions are especially common in fulminating cases. Lymphadenitis may occur and may progress to suppuration. HIV-infected persons with disseminated disease have a higher incidence of miliary infiltrates, lymphadenopathy, and meningitis, but skin lesions are uncommon.

Laboratory Findings

In primary coccidioidomycosis, there may be moderate leukocytosis and eosinophilia. Serologic testing is useful for both diagnosis and prognosis. The immunodiffusion tube precipitin test detects IgM antibodies and is useful for diagnosis early in the disease process. Historically, a persistent rising IgG complement fixation titer (1:16) has been considered suggestive of disseminated disease; in addition, complement fixation titers can be used to assess the adequacy of therapy. Serum complement fixation titer may be low when there is meningitis but no other disseminated disease. In patients with HIV-related coccidioidomycosis, the false-negative rate may be as high as 30%.

Demonstrable complement-fixing antibodies in spinal fluid are diagnostic of coccidioidal meningitis. These are found in over 90% of cases. Spinal fluid findings include increased cell count with lymphocytosis and reduced glucose. Spinal fluid culture is positive in approximately 30% of meningitis cases. Spherules filled with endospores may be found in biopsy specimens; though they are not infectious, they convert to the highly contagious arthroconidia when grown in culture media. Blood cultures are rarely positive. A urine antigen test similar to that for histoplasmosis has been developed for coccidioidomycosis; however, there is cross-reactivity of this test for the two diseases.

Imaging

Radiographic findings vary, but patchy, nodular pulmonary infiltrates and thin-walled cavities are most common. Hilar lymphadenopathy may be visible and is seen in localized disease; mediastinal lymphadenopathy suggests dissemination. There may be pleural effusions and lytic lesions in bone with accompanying complicated soft-tissue collections.

Treatment

General symptomatic therapy is given as needed for disease limited to the chest with no evidence of progression. For progressive pulmonary or extrapulmonary disease, amphotericin B intravenously is used although oral azoles may be used for mild cases (see Chapter e1: Anti-infective Chemotherapeutic & Antibiotic Agents). Therapy should be continued, with duration of therapy determined by a declining complement fixation titer and a favorable clinical response. For meningitis, treatment usually is with high-dose oral fluconazole (400–800 mg/d) although lumbar or cisternal intrathecal administration of amphotericin B daily in increasing doses up to 1–1.5 mg/d is used initially by some physicians or in cases refractory to fluconazole. Systemic therapy with amphotericin B, 0.6 mg/kg/d intravenously, is generally given concurrently with intrathecal therapy but is not sufficient alone for the treatment of meningeal disease. Voriconazole or posaconazole may be alternatives to intrathecal amphotericin B in patients who do not respond to fluconazole. Once the patient is clinically stable, oral therapy with an azole, usually lifelong, is the recommended alternative to intrathecal amphotericin B therapy.

Fluconazole, 200–400 mg orally once daily, or itraconazole, 400 mg orally daily divided into two doses, may be given for disease in the chest, bones, and soft tissues; however, therapy must be continued for 6 months or longer after the disease is inactive to prevent relapse. Response to therapy should be monitored by following the progressive decrease in serum complement fixation titers.

Thoracic surgery is occasionally indicated for giant, infected, or ruptured cavities. Surgical drainage is necessary for managemen of soft tissue abscesses and bone disease. Amphotericin B, 1 mg/kg/d intravenously, is advisable following extensive surgical manipulation of infected tissue until the disease is inactive, whereupon therapy may be continued with an azole.

Prognosis

The prognosis for patients with limited disease is good, but persistent pulmonary cavities may cause complications such as hemoptysis or rupture producing pyopneumothorax. Nodules, cavities, and fibrotic residuals may rarely progress after long periods of stability or regression. Serial complement fixation titers should be performed after therapy for patients with coccidioidomycosis; rising titers warrant reinstitution of therapy because relapse is likely. Late central nervous system complications of adequately treated meningitis include cerebral vasculitis and hydrocephalitis that may require shunting. Disseminated and meningeal forms still have mortality rates exceeding 50% in the absence of therapy.

Durkin M et al. Diagnosis of coccidioidomycosis with use of the *Coccidioides* antigen enzyme immunoassay. Clin Infect Dis. 2008 Oct 15;47(8):e69–73. [PMID: 18781884]

Pneumocystosis (*Pneumocystis jiroveci* Pneumonia)

Essentials of Diagnosis

- Fever, dyspnea, nonproductive cough.
- Bilateral diffuse interstitial disease without hilar adenopathy by chest radiograph.
- Bibasilar crackles on auscultation in many cases; others have no findings.
- Reduced partial pressure of oxygen.
- *P jiroveci* in sputum, bronchoalveolar lavage fluid, or lung tissue.

General Considerations

Pneumocystis jiroveci, the *Pneumocystis* species that affects humans, is distributed worldwide. Although symptomatic *P jiroveci* disease is rare in the general population, serologic evidence indicates that asymptomatic infections have occurred in most persons by a young age. The overt infection is an acute interstitial plasma cell pneumonia that occurs with high frequency among two groups: (1) as epidemics of primary infections among premature or debilitated or marasmic infants on hospital wards in underdeveloped parts of the world, and (2) as sporadic cases among older children and adults who have an abnormal or altered cellular immune status. Cases occur most commonly in patients with cancer or severe malnutrition and debility, in patients treated with immunosuppressive or cytotoxic drugs or irradiation for the management of organ transplants and cancer and, most frequently, in patients with AIDS (see Chapter 31: HIV Infection & AIDS).

The mode of transmission in primary infection is unknown, but the evidence suggests airborne transmission. Following asymptomatic primary infection, latent and presumably inactive organisms are sparsely distributed in the alveoli. Whether acute infection in older children and adults results from de novo infection or from reactivation of latent infection is not entirely clear, although both mechanisms probably contribute.

Pneumocystis pneumonia occurs in up to 80% of AIDS patients not receiving prophylaxis and is a major cause of death. Its incidence increases in direct proportion to the fall in CD4 cells, with most cases occurring at CD4 cell counts below 200/mcL. Dissemination of the infection to tissues other than the lung is rare. In non-AIDS patients receiving immunosuppressive therapy, symptoms frequently begin after corticosteroids have been tapered or discontinued.

Clinical Findings

Symptoms and Signs

Findings are usually limited to the pulmonary parenchyma; extrapulmonary disease is reported rarely. In the sporadic form of the disease associated with deficient cell-mediated immunity, the onset is abrupt, with fever, tachypnea, shortness of breath, and usually nonproductive cough. Pulmonary physical findings may be slight and disproportionate to the degree of illness and the radiologic findings; many patients have bibasilar crackles, but others do not. Without treatment, the course is usually one of rapid deterioration and death. Adult patients may present with spontaneous pneumothorax, usually in patients with previous episodes or those receiving aerosolized pentamidine prophylaxis. Patients with AIDS will usually have other evidence of HIV-associated disease, including fever, fatigue, and weight loss, for weeks or months preceding the illness.

Laboratory Findings

Chest radiographs most often show diffuse "interstitial" infiltration, which may be heterogeneous, miliary, or patchy early in infection. There may also be diffuse or focal consolidation, cystic changes, nodules, or cavitation within nodules (see x-ray). Pleural effusions are not seen. About 5–10% of patients with *Pneumocystis* pneumonia have normal chest films. High-resolution chest CT scans may be quite suggestive of *P jiroveci* pneumonia, helping distinguish it from other causes of pneumonia.

Fig.

Pneumatoceles in *Pneumocystis carinii* pneumonia. Two large adjacent pneumatoceles with thin-walled sharp borders are seen in the left upper lobe. This is superimposed on small nodular densities scattered in the perihilar regions with fine perihilar infiltrates consistent with typical *P carinii* pulmonary involvement. Pneumatoceles are characteristic of pneumocystis pneumonia and may account for concurrent pneumothorax. (Courtesy of H Goldberg.)

Arterial blood gas determinations usually show hypoxemia with hypocapnia but may be normal; however, rapid desaturation occurs if patients are exercised before samples are drawn. Isolated elevation or rising levels of serum LDH are very sensitive but not specific findings for *P jiroveci.* Lymphopenia with depleted CD4 lymphocytes is common. Serologic tests, including tests to detect antigenemia, are not helpful in diagnosis.

Specific diagnosis depends on morphologic demonstration of the organisms in clinical specimens using specific stains. The organism cannot be cultured. Adequate specimens can sometimes be obtained with induced sputum by having patients inhale an aerosol of hypertonic saline (3%) produced by an ultrasonic nebulizer. Specimens are then stained with Giemsa stain or methenamine silver, either of which allows detection of cysts. The use of monoclonal antibody with immunofluorescence has increased the sensitivity of diagnosis. Alternative techniques for obtaining specimens include bronchoalveolar lavage (sensitivity 86–97%) followed by transbronchial lung biopsy (85–97%), if necessary. Open lung biopsy and needle lung biopsy are infrequently done but may need to be performed to diagnose a granulomatous form of *Pneumocystis* pneumonia. The polymerase chain reaction (PCR) test for the detection of *P jiroveci* appears to be overly sensitive in that many patients without *Pneumocystis* pneumonia will have a positive PCR on respiratory samples.

Treatment

See Table 31–5. It is appropriate to start empiric therapy for *P jiroveci* pneumonia if the disease is suspected clinically; however, in both AIDS patients and non-AIDS patients with mild to moderately severe disease, continued treatment should be based on a proved diagnosis because of clinical overlap with other infections, the toxicity of therapy, and the possible coexistence of other infectious organisms. Oral trimethoprim-sulfamethoxazole (TMP-SMZ) is the preferred agent because of its low cost and excellent bioavailability in both AIDS patients and non-AIDS patients with mild to moderately severe disease. Patients suffering from nausea and vomiting or intractable diarrhea should be given intravenous TMP-SMZ until they can tolerate the oral formulation. The best-studied second-line option is a combination of clindamycin and primaquine, although dapsone/trimethoprim, pentamidine, and atovaquone have also been used. Therapy should be continued with the selected drug for at least 5–10 days before considering changing agents, as fever, tachypnea, and pulmonary infiltrates persist for 4–6 days after starting treatment. Some patients have a transient worsening of their disease during the first 3–5 days, which may be related to an inflammatory response secondary to the presence of dead or dying organisms. Early addition of corticosteroids may attenuate this response (see Chapter 31: HIV Infection & AIDS). Some clinicians prefer to treat episodes of AIDS-associated *Pneumocystis* pneumonia for 21 days rather than the usual 14 days recommended for non-AIDS cases.

Trimethoprim-Sulfamethoxazole

The dosage is TMP 20 mg/kg (12–15 mg/kg may decrease side effects without decreasing efficacy) and SMZ 100 mg/kg given orally or intravenously daily in three or four divided doses for 14–21 days. Adverse reactions are generally those of the sulfonamide component. Patients with AIDS have a high frequency of hypersensitivity reactions (approaching 50%), which may include fever, rashes (sometimes severe), malaise, neutropenia, hepatitis, nephritis, thrombocytopenia, hyperkalemia, and hyperbilirubinemia.

Clindamycin/Primaquine

Although there are strong data indicating that trimethoprim-sulfamethoxazole is optimal first-line therapy for *Pneumocystis* pneumonia, the data on alternative agents is less clear. A meta-analysis suggested that clindamycin, 600 mg three times daily, plus primaquine, 15 mg/d, is the best second-line therapy with superior results when compared with pentamidine. Primaquine may cause hemolytic anemia in patients with glucose-6-phosphate dehydrogenase (G6PD)-deficiency.

Pentamidine Isethionate

The use of pentamidine has decreased as alternative agents have been studied. This drug is administered intravenously (preferred) or intramuscularly as a single dose of 3 mg (salt)/kg/d for 14–21 days. Pentamidine causes side effects in nearly 50% of patients. Hypoglycemia (often clinically inapparent), hyperglycemia, hyponatremia, and delayed nephrotoxicity with azotemia may occur. Rarely, a variety of other severe adverse reactions may occur, including anemia, thrombocytopenia, ventricular arrhythmias, and fatal pancreatitis. Blood glucose levels should be monitored. Inadvertent rapid intravenous infusion may cause precipitous hypotension.

Atovaquone

Atovaquone has been approved by the US Food and Drug Administration (FDA) for patients with mild to moderate disease who cannot tolerate TMP-SMZ or pentamidine, but failure is reported in 15–30% of cases. Mild side effects are common, but no serious reactions have been reported. The dosage is 750 mg three times daily for 21 days.

Other Drugs

Dapsone, 100 mg/d, plus trimethoprim 15 mg/kg/d, in three divided doses daily, is an alternative oral regimen for mild to moderate disease or for continuation of therapy after intravenous therapy is no longer needed.

Prednisone

Prednisone is given for moderate to severe pneumonia (when PaO_2 on admission is < 70 mm Hg or oxygen saturation is < 90%) in conjunction with antimicrobials; its use during the first 72 hours of therapy for severe *Pneumocystis* pneumonia prevents deterioration in oxygenation and improves survival. The dosage of prednisone is 40 mg twice daily for 5 days, then 40 mg daily for 5 days, and then 20 mg daily until therapy is completed.

Supportive Care

Oxygen therapy is indicated to maintain the oxygen saturation over 90% by pulse oximetry.

Prevention

Primary prophylaxis for *Pneumocystis* pneumonia in HIV-infected patients should be given to persons with CD4 counts < 200 cells/mcL, a CD4 percentage below 14%, or weight loss or oral candidiasis (see Table 31–4). Primary prophylaxis is often used in patients with hematologic malignancy and transplant recipients. The occurrence of *P jiroveci* pneumonia while on prophylaxis may be associated with development of resistance to TMP-SMZ. Patients with a history of *Pneumocystis* pneumonia should receive secondary prophylaxis until they have had a durable virologic response to antiretroviral therapy for at least 3–6 months and maintain a CD4 count of > 250 cells/mcL.

Prognosis

In the absence of early and adequate treatment, the fatality rate for the endemic infantile form of *Pneumocystis* pneumonia is 20–50%; for the sporadic form in immunodeficient persons, the fatality rate is nearly 100%. Early treatment reduces the mortality rate to about 3% in the former and 10–20% in AIDS patients. The mortality rate in other immunodeficient patients is still 30–50%, probably because of failure to make a timely diagnosis. In immunodeficient patients who do not receive prophylaxis, recurrences are common (30% in AIDS).

Davis JL et al. *Pneumocystis* colonisation is common among hospitalised HIV-infected patients with non-*Pneumocystis* pneumonia. Thorax. 2008 Apr;63(4):329–34. [PMID: 18024536]

Cryptococcosis

Essentials of Diagnosis

- Most common cause of fungal meningitis.
- Predisposing factors: Hodgkin disease, corticosteroid therapy, HIV infection, transplant recipients.
- Symptoms of headache, abnormal mental status; meningismus seen occasionally, though rarely in HIV-infected patients.
- Demonstration of capsular polysaccharide antigen in cerebrospinal fluid diagnostic; 95% of HIV-infected and solid-organ transplant patients also have a positive serum antigen.

General Considerations

Cryptococcosis is mainly caused by *Cryptococcus neoformans*, an encapsulated budding yeast that has been found worldwide in soil and on dried pigeon dung. *Cryptococcus gattii* is a closely related species that also causes disease in humans although *C gattii* may affect more immunocompetent persons.

Infections are acquired by inhalation. In the lung, the infection may remain localized, heal, or disseminate. Clinically apparent cryptococcal pneumonia rarely develops in immunocompetent persons. Progressive lung disease and dissemination most often occur in the setting of cellular immunodeficiency, including underlying hematologic cancer under treatment, Hodgkin disease, long-term corticosteroid therapy, solid-organ transplant, or HIV infection.

Clinical Findings

Symptoms and Signs

Pulmonary disease ranges from simple nodules to widespread infiltrates leading to respiratory failure. Disseminated disease may involve any organ, but central nervous system disease predominates. Headache is usually the first symptom of meningitis. Confusion and other mental status changes as well as cranial nerve abnormalities, nausea, and vomiting may be seen as the disease progresses. Nuchal rigidity and meningeal signs occur about 50% of the time but are uncommon in HIV-infected patients. Communicating hydrocephalus may complicate the course. Primary *C neoformans* infection of the skin may mimic bacterial cellulitis, especially in immunocompromised persons. Clinical worsening associated with improved immunologic status has been reported in HIV-positive and transplant patients with cryptococcosis; this entity has been labeled the immune reconstitution inflammatory syndrome (IRIS).

Laboratory Findings

Respiratory tract disease is diagnosed by culture of respiratory secretions or pleural fluid. For suspected meningeal disease, lumbar puncture is the preferred diagnostic procedure. Spinal fluid findings include increased opening pressure, variable pleocytosis, increased protein, and decreased glucose, though as many as 50% of AIDS patients have no pleocytosis. Gram stain of the cerebrospinal fluid usually reveals budding, encapsulated fungal cells. Cryptococcal capsular antigen in cerebrospinal fluid and culture together establish the diagnosis over 90% of the time. Patients with AIDS often have the antigen in both cerebrospinal fluid and serum, and extrameningeal disease (lungs, blood, urinary tract) is common. In patients with AIDS, the serum cryptococcal antigen is also a sensitive screening test for meningitis, being positive in over 95% of cases. MRI is more sensitive than CT in finding central nervous system abnormalities such as cryptococcomas.

Treatment

Because of decreased efficacy and development of resistance, initial therapy with an azole is not recommended for treatment of acute cryptococcal meningitis. Consequently, treatment regimens using amphotericin B should be started. However, there has been a trend away from prolonged amphotericin B therapy regimens, particularly in HIV-infected patients. Thus, amphotericin B, 0.7–1 mg/kg/d intravenously is used for 14 days, followed by an additional 8 weeks of fluconazole, 400 mg/d orally. This regimen has been quite effective, achieving clinical responses and cerebrospinal fluid sterilization in about 70% of patients. The addition of flucytosine has been associated with improved survival, but toxicity is common. Flucytosine is administered orally at a dose of 100 mg/kg/d divided into four equal doses and given every 6 hours. Hematologic parameters should be closely monitored during flucytosine therapy. Repeated lumbar punctures or ventricular shunting should be performed to relieve high cerebrospinal fluid pressures or if hydrocephalus is a complication. Failure to adequately relieve raised intracranial pressure is a major cause of morbidity and mortality. The end points for amphotericin B therapy and for switching to oral fluconazole are a favorable clinical response (decrease in temperature; improvement in headache, nausea, vomiting, and mini-mental status scores), improvement in cerebrospinal fluid biochemical parameters and, most importantly, conversion of cerebrospinal fluid culture to negative.

A similar approach is reasonable for patients with cryptococcal meningitis in the absence of AIDS, though the mortality rate is considerably higher. Lipid amphotericin B preparations appear to have equivalent efficacy with reduced nephrotoxicity. Therapy is generally continued until cerebrospinal fluid cultures become negative and cerebrospinal fluid antigen titers are below 1:8.

Maintenance antifungal therapy is important after treatment of an acute episode in HIV-related cases, since otherwise the rate of relapse is greater than 50%. Fluconazole, 200 mg/d, is the maintenance therapy of choice, decreasing the relapse rate approximately tenfold compared with placebo and threefold compared with weekly amphotericin B in patients whose cerebrospinal fluid has been sterilized by the induction therapy. After successful therapy of cryptococcal meningitis, it is possible to discontinue secondary prophylaxis with fluconazole in individuals with AIDS who have had a satisfactory response to antiretroviral therapy (eg, CD4 cell count > 100–200 cells/mcL for at least 6 months). Among practitioners treating patients without AIDS, there has been a trend in recent years to prescribe a course (eg, 6–12 months) of fluconazole as maintenance therapy following successful treatment of the acute illness; recently published guidelines suggest this as an option.

Prognosis

Factors that indicate a poor prognosis include the activity of the predisposing conditions, older age, organ failure, lack of spinal fluid pleocytosis, high initial antigen titer in either serum or cerebrospinal fluid, decreased mental status, increased intracranial pressure, and the presence of disease outside the nervous system.

Aspergillosis

Essentials of Diagnosis

- Most common cause of invasive fungal infection in stem cell or organ transplant patients.
- Predisposing factors: leukemia, bone marrow or organ transplant, late HIV infection.

- Pulmonary, sinus, and CNS are most common disease sites.
- Demonstration of galactomannan or -D-glucan in serum or other body fluid samples contributes to early diagnosis and treatment.

General Considerations

Aspergillus fumigatus is the usual cause of aspergillosis, though many species of *Aspergillus* may cause a wide spectrum of disease. The lungs, sinuses, and brain are the organs most often involved. Clinical illness results either from an aberrant immunologic response or tissue invasion.

Clinical Findings

Allergic Bronchopulmonary Aspergillosis

This form of aspergillosis occurs in patients with preexisting asthma who develop worsening bronchospasm and fleeting pulmonary infiltrates accompanied by eosinophilia, high levels of IgE, and IgG *Aspergillus* precipitins in the blood. It also may complicate cystic fibrosis.

Invasive Aspergillosis

Invasive manifestations may be seen in immunocompetent or only mildly immunocompromised adults. These include chronic **sinusitis**, colonization of preexisting pulmonary cavities **(aspergilloma)** (see x-ray), and chronic necrotizing pulmonary aspergillosis.

Fig.

Pulmonary aspergillosis. The left lung contains multiple ill-defined lesions adjacent to the left hilum. These appear to be separate lesions that have become confluent and are one of the manifestations of pulmonary aspergillosis. Some atelectasis of the left base is also present, best seen because of elevation of the left hemidiaphragm. (Courtesy of H Goldberg.)

Sinusitis

Sinus involvement is usually diagnosed histologically after patients with chronic sinus disease undergo surgery.

Aspergillomas

Aspergillomas of the lung occur when preexisting lung lesions become secondarily colonized with *Aspergillus* species. These may be found by incidental radiographic studies but may also present with significant hemoptysis.

Chronic necrotizing aspergillosis

This invasive manifestation is a relatively rare disease seen in patients with some degree of immunocompromise and presents with a protracted course compared with the more common acute invasive form of the disease. Fibrosis and cavity formation may be prominent.

Life-threatening invasive aspergillosis

Severe invasive aspergillosis most commonly occurs in profoundly immunodeficient patients, particularly in patients who have undergone hematopoietic stem cell transplants and in those with prolonged, severe neutropenia. Specific risk factors in patients who have undergone a hematopoietic stem cell transplant include cytopenias, corticosteroid use, iron overload, cytomegalovirus disease, and graft-versus-host disease. Pulmonary disease is most common, with patchy infiltration leading to a severe necrotizing pneumonia (see x-ray). Invasive sinus disease also occurs. There is often tissue infarction as the organism grows into blood vessels; clues to this are the development of pleuritic chest pain and elevation of serum LDH. At any time, there may be hematogenous dissemination to the central nervous system, skin, and other organs. Early diagnosis and reversal of any correctable immunosuppression are essential. Blood cultures have very low yield. Detection of galactomannan by enzyme-linked immunosorbent assay (ELISA) or -D-glucan, or both, has been used for the early diagnosis of invasive disease, though multiple determinations should be done. Higher galactomannan levels are correlated with increased mortality. False-positive galactomannan tests have been reported in patients receiving -lactam antibiotics. Isolation of *Aspergillus* from pulmonary secretions does not necessarily imply invasive disease, although its positive predictive value increases with more advanced immunosuppression. Therefore, a definitive diagnosis requires demonstration of *Aspergillus* in tissue or culture from a sterile site. CT scan of the chest may show characteristics quite suggestive of invasive aspergillosis (eg, "halo sign").

Fig.

Invasive aspergillosis. A central venous line is seen with its tip at about the level of the superior vena cava. An ill-defined, more marginated oval-shaped density is seen adjacent to the right hilum. This occurred acutely in this immunocompromised patient and was found to be caused by invasive aspergillosis. (Courtesy of H Goldberg.)

Prevention

The high mortality rate and difficulty in diagnosis of invasive aspergillosis often leads clinicians to institute prophylactic therapy for patients with profound immunosuppression. The best-studied agents include fluconazole, itraconazole, voriconazole, and posaconazole, although patient and agent selection criteria remain undefined. Widespread use of broad-spectrum azoles raises concern for development of invasive disease by highly resistant fungi.

Treatment

Allergic Bronchopulmonary Aspergillosis

For acute exacerbations, oral prednisone is begun at a dose of 1 mg/kg/d and then tapered slowly over several months. Itraconazole at a dose of 200 mg daily for 16 weeks appears to improve pulmonary function and decrease corticosteroid requirements in these patients, although voriconazole may become the preferred oral agent.

Invasive Aspergillosis

Sinusitis

These patients may require protracted courses of antifungals (itraconazole, 200 mg twice daily, for weeks to months) in addition to the surgical debridement.

Aspergilloma

The most effective therapy for symptomatic aspergilloma remains surgical resection.

Chronic necrotizing aspergillosis

Although it would be reasonable to institute therapy targeting *Aspergillus*, response to such therapy is not clear.

Life-threatening invasive aspergillosis

When severe invasive aspergillosis is considered clinically likely or is demonstrable by laboratory testing, rapid institution of voriconazole, high doses of amphotericin B, or caspofungin may be life-saving. Voriconazole (6 mg/kg intravenously twice on day 1, then 4 mg/kg/d thereafter) has been shown to be more effective, improve survival, and be associated with fewer severe side effects than conventional amphotericin B when used as initial therapy in invasive aspergillosis. Oral dosing of voriconazole at 4 mg/kg twice daily can be used for less serious infections or as a step-down strategy after intravenous therapy. Some experts believe that intravenous lipid preparations of amphotericin B (3–5 mg/kg/d) should be used preferentially in this setting because they are better tolerated and can be given at higher doses.

Caspofungin (70 mg intravenously on day 1, then 50 mg/d thereafter) is approved for the treatment of invasive aspergillosis in patients who do not respond to or are intolerant of other treatments. Other options include micafungin (100–150 mg/d intravenously) and posaconazole (200 mg orally four times daily). In critically ill patients who are not responding to conventional antifungal treatment, there may be a role for the addition of caspofungin to amphotericin B or voriconazole therapy, although randomized trials are lacking. Based on promising results in neutropenic patients with invasive pulmonary aspergillosis, surgical resection warrants further study. The mortality rate of pulmonary or disseminated disease in the immunocompromised patient remains well above 50%, particularly in patients with refractory neutropenia.

America. Clin Infect Dis. 2008 Feb 1;46(3):327–60. [PMID: 18177225]

Mucormycosis

The term "mucormycosis" (zygomycosis, phycomycosis) is applied to opportunistic infections caused by members of the genera *Rhizopus*, *Mucor*, *Absidia*, and *Cunninghamella*. Predisposing conditions include diabetic ketoacidosis, chronic kidney disease, desferoxamine therapy, and treatment with corticosteroids or cytotoxic drugs. These organisms appear in tissues as broad, branching nonseptate hyphae. Biopsy with histologic examination is almost always required for diagnosis; cultures are frequently negative. Invasive disease of the sinuses, orbits, and the lungs may occur. Widely disseminated disease is seen in patients who have received aggressive chemotherapy and broad-spectrum antifungal prophylaxis. A prolonged course of high-dosage amphotericin B (1–1.5 mg/kg/d intravenously) or a lipid preparation of amphotericin B should be started early. Based on in vitro susceptibility and reports of successful salvage therapy, there may be a role for posaconazole in the treatment of these infections, but other azoles are likely to be ineffective. There are limited data suggesting beneficial synergistic activity when amphotericin and caspofungin are used in combination for mucormycosis. Ongoing studies are assessing whether iron chelation therapy with deferasirox may also be helpful. Control of diabetes and other underlying conditions, along with extensive repeated surgical removal of necrotic, nonperfused tissue, is essential. Even when these measures are introduced in a timely fashion, the prognosis is poor, with a 30–50% mortality rate for localized disease and higher rates in disseminated cases.

Reed C et al. Combination polyene-caspofungin treatment of rhino-orbital-cerebral mucormycosis. Clin Infect Dis. 2008 Aug 1;47(3):364–71. [PMID: 18558882]

Blastomycosis

Blastomycosis occurs most often in men infected during occupational or recreational activities out of doors and in a geographically limited area of the south central and midwestern United States and Canada. Disease usually occurs in immunocompetent individuals.

Pulmonary infection is most common and may be asymptomatic. When dissemination takes place, lesions are most frequently seen in the skin, bones, and urogenital system.

Cough, moderate fever, dyspnea, and chest pain are common. These may resolve or progress, with bloody and purulent sputum production, pleurisy, fever, chills, loss of weight, and prostration. Radiologic studies, either chest radiographs or CT scans, usually reveal airspace consolidations or masses.

Raised, verrucous cutaneous lesions are commonly present in disseminated blastomycosis. Bones—often the ribs and vertebrae—are frequently involved. Lesions appear to be both destructive and proliferative on radiography. Epididymitis, prostatitis, and other involvement of the male urogenital system may occur. Although they do not appear to be at greater risk for acquisition of disease, infection in HIV-infected persons may progress rapidly, with dissemination common.

Laboratory findings usually include leukocytosis and anemia, though these are not specific. The organism is found in clinical specimens, such as expectorated sputum or tissue, as a thick-walled cell 5–20 mcm in diameter that may have a single broad-based bud. It grows readily on culture. Serologic tests are not well standardized. A urinary antigen test is available, but it has some cross reactivity with *Histoplasma;* consequently, its usefulness in diagnosis and in assessing response to therapy is unclear.

Itraconazole, 200–400 mg/d orally for at least 2–3 months, is the therapy of choice for nonmeningeal disease, with a response rate of over 80%. Amphotericin

B, 0.7–1.0 mg/kg/d intravenously (or lipid formulation amphotericin B), is given for severe disease, treatment failures, or central nervous system involvement.

Clinical follow-up for relapse should be made regularly for several years so that therapy may be resumed or another drug instituted.

Chapman SW et al. Clinical practice guidelines for the management of blastomycosis: 2008 update by the Infectious Diseases Society of America. Clin Infect Dis. 2008 Jun 15;46(12):1801–12. [PMID: 18462107]

Hussein R et al. Blastomycosis in the mountainous region of Northeast Tennessee. Chest. 2008 Nov 18 2009 April;135(4): 1019–23. [PMID: 19017881]

Paracoccidioidomycosis (South American Blastomycosis)

Paracoccidioides brasiliensis infections have been found only in patients who have resided in South or Central America or Mexico. Long asymptomatic periods enable patients to travel far from the endemic areas before developing clinical problems. Weight loss, pulmonary complaints, or mucosal ulcerations are the most common symptoms. Cutaneous papules may ulcerate and enlarge both peripherally and deeper into the subcutaneous tissue. Differential diagnosis includes mucocutaneous leishmaniasis and syphilis. Extensive coalescent ulcerations may eventually result in destruction of the epiglottis, vocal cords, and uvula. Extension to the lips and face may occur. Eating and drinking are extremely painful. Skin lesions may occur, usually on the face. Variable in appearance, they may have a necrotic central crater with a hard hyperkeratotic border. Lymph node enlargement may follow mucocutaneous lesions, eventually ulcerating and forming draining sinuses; in some patients, it is the presenting symptom. Hepatosplenomegaly may be present as well. The extensive ulceration of the upper gastrointestinal tract may prevent caloric intake and result in cachexia.

Laboratory findings are nonspecific. Serology by immunodiffusion is positive in 98% of cases. Complement fixation titers correlate with progressive disease and fall with effective therapy. The fungus is found in clinical specimens as a spherical cell that may have many buds arising from it. If direct examination does not reveal the organism, biopsy with Gomori staining may be helpful.

Itraconazole, 100 mg twice daily, is the treatment of choice and generally results in a clinical response within 1 month and effective control after 2–6 months. Voriconazole, 200 mg twice daily, appears to be as effective as itraconazole.

de Camargo ZP. Serology of paracoccidioidomycosis. Mycopathologia. 2008 Apr–May;165(4–5):289–302.

[PMID: 18777635]

Sporotrichosis

Sporotrichosis is a chronic fungal infection caused by *Sporothrix schenckii*. It is worldwide in distribution; most patients have had contact with soil, sphagnum moss, or decaying wood. Transmission from animals to humans has also been reported. Infection takes place when the organism is inoculated into the skin—usually on the hand, arm, or foot, especially during gardening.

The most common form of sporotrichosis begins with a hard, nontender subcutaneous nodule. This later becomes adherent to the overlying skin and ulcerates. Within a few days to weeks, similar nodules develop along the lymphatics draining this area, and these may ulcerate as well.

Disseminated sporotrichosis is rare in the immunocompetent person but may present with widespread cutaneous, lung, bone, joint, and central nervous system involvement in immunocompromised patients, especially those with AIDS and alcohol abuse.

Cultures are needed to establish diagnosis. Antibody tests may be useful for diagnosis of disseminated disease, especially meningitis.

Itraconazole, 200–400 mg orally daily for several months, is now the treatment of choice for localized disease and some milder cases of disseminated disease. Terbinafine, 500 mg twice daily, also appears to have good efficacy in lymphocutaneous disease. Amphotericin B intravenously, 1–2 g, is used for severe systemic infection. Surgery is usually contraindicated except for simple aspiration of secondary nodules. Joint involvement may require arthrodesis.

The prognosis is good for lymphocutaneous sporotrichosis; pulmonary, joint, and disseminated disease respond less favorably.

Schubach A. Epidemic sporotrichosis. Curr Opin Infect Dis. 2008 Apr;21(2):129–33. [PMID: 18317034]

Penicillium marneffei Infections

Penicillium marneffei is a dimorphic fungus, endemic in southeast Asia, that causes systemic infection in both healthy and immunocompromised hosts. There have been increasing reports of travelers with advanced AIDS returning from southeast Asia with disseminated infection. Clinical manifestations include fever, generalized umbilicated papular rash, lymphadenopathy, cough, and diarrhea. Diagnosis is made by identification of the organism on smears or histopathologic specimens or by culture, where the fungus produces a characteristic red pigment. The best sites for isolation of the fungus include the skin, blood, bone marrow, respiratory tract, and lymph nodes. Antigen and antibody tests have been developed in endemic regions. Patients with mild to moderate infection can be treated with itraconazole, 400 mg divided into two doses daily by mouth for 8 weeks. Amphotericin B, 0.5–0.7 mg/kg/d, is the drug of choice for severe disease and should be continued until patients have had a satisfactory clinical response, at which time they can be switched to itraconazole. Because the relapse rate after successful treatment is 30%, maintenance therapy with itraconazole, 200–400 mg daily, is indicated indefinitely.

Ustianowski AP et al. *Penicillium marneffei* infection in HIV. Curr Opin Infect Dis. 2008 Feb;21(1):31–6. [PMID: 18192783]

Chromoblastomycosis (Chromomycosis)

Chromoblastomycosis is a chronic, principally tropical cutaneous infection usually affecting young men who are agricultural workers and caused by several species of closely related black molds; *Cladophialophora carrionii* and *Fonsecaea pedrosoi* are the most common etiologic agents.

Lesions usually follow puncture wounds and are slowly progressive, occurring most frequently on a lower extremity. The lesion begins as a papule or ulcer. Over months to years, papules enlarge to become vegetating, papillomatous, verrucous elevated nodules. Satellite lesions may appear along the lymphatics. There may be secondary bacterial infection. Elephantiasis may result.

The fungus is seen as brown, thick-walled, spherical, sometimes septate cells in potassium hydroxide preparations of pus or skin scrapings, which are quite sensitive for diagnosis. The type of reproduction found in culture determines the species.

Itraconazole, 200–400 mg/d orally for 6–18 months, achieves a response rate of 65%. Response rates may be improved by the addition to itraconazole of flucytosine, 100–150 mg/kg/d by mouth divided into four doses. Terbinafine at 500 mg/d may have similar efficacy to itraconazole. Cryosurgery alone for smaller lesions or combined with itraconazole for larger lesions is beneficial.

Queiroz-Telles F et al. Chromoblastomycosis: an overview of clinical manifestations, diagnosis and treatment. Med Mycol. 2009 Feb;47(1):3–15. [PMID: 19085206]

Mycetoma (Maduromycosis & Actinomycetoma)

Mycetoma is a chronic local, slowly progressive destructive infection, usually involving the foot, that begins in subcutaneous tissues, frequently after localized trauma, and then spreads to contiguous structures. Maduromycosis (also known as eumycetoma) is the term used to describe mycetoma caused by the true fungi and by phylogenetically diverse organisms. Actinomycotic mycetoma is caused by *Nocardia* and *Actinomadura* species. The disease begins as a papule, nodule, or abscess that over months to years progresses slowly to form multiple abscesses and sinus tracts ramifying deep into the tissue. Secondary bacterial infection may result in large open ulcers. Radiographs may show destructive changes in the underlying bone. Tissue Gram stain reveals fine branching hyphae with actinomycotic mycetoma. Larger hyphae are seen with fungal mycetoma; the causative species can often be identified by the color of the characteristic grains within the infected tissues.

The prognosis is good for patients with actinomycetoma, since they usually respond well to sulfonamides and sulfones, especially if treated early. TMP-SMZ, 160/800 mg orally twice a day, or dapsone, 100 mg twice daily after meals, has been reported to be effective. Streptomycin, 14 mg/kg/d intramuscularly, may be useful during the first month of therapy. All oral medications must be taken for months and continued for several months after clinical cure to prevent relapse. Debridement assists healing.

The prognosis for maduromycosis is poor, though surgical debridement along with prolonged itraconazole therapy may result in a response rate of 70%. The various etiologic agents may respond differently to antifungal agents, so culture results are invaluable. Amputation is necessary in far advanced cases.

Ameen M et al. Developments in the management of mycetomas. Clin Exp Dermatol. 2009 Jan;34(1):1–7. [PMID: 19076788]

Other Opportunistic Mold Infections

Fungi previously considered to be harmless colonizers, including *Pseudallescheria boydii (Scedosporium apiospermum),Scedosporium prolificans*, *Fusarium*, *Paecilomyces*, *Trichoderma longibrachiatium*, and *Trichosporon*, are emerging as significant pathogens in immunocompromised patients. This occurs most often in patients being treated for hematopoietic malignancies and in those receiving broad-spectrum antifungal prophylaxis. Infection may be localized in the skin, lungs, or sinuses, or widespread disease may appear with lesions in multiple organs. Colonization of old cavitary disease may cause minimal symptoms or may precede dissemination with meningitis or brain abscesses. Endocarditis occurs more commonly in injection drug users. Sinus infection may cause bony erosion. Infection in subcutaneous tissues following traumatic implantation may develop as a well-circumscribed cyst or as an ulcer.

Nonpigmented septate hyphae are seen in tissue and are indistinguishable from those of *Aspergillus* when infections are due to *S apiospermum* or species of *Fusarium*, *Paecilomyces*, *Penicillium*, or other hyaline molds. Spores or mycetoma-like granules are rarely present in tissue.

Infection by any of a number of black molds is designated as phaeohyphomycosis. These black molds (eg, *Exophiala, Bipolaris, Cladophialophora, Curvularia, Alternaria*) are common in the environment, especially on decaying vegetation. Human disease due to these agents is rarely encountered but may result in soft tissue abscesses due to traumatic inoculation or may occur as a sequela of chronic sinusitis or profound immunosuppression. In tissues of patients with phaeohyphomycosis, the mold is seen as black or faintly brown hyphae, yeast cells, or both. Culture on appropriate medium is needed to identify the agent. Histologic demonstration of these organisms is definitive evidence of invasive infection; positive cultures must be interpreted cautiously and not assumed to be contaminants in immunocompromised hosts. Some isolates are sensitive to antifungal agents. The differentiation of *S apiospermum* and *Aspergillus* is particularly important, since the former is uniformly resistant to amphotericin B but may be sensitive to azole antifungals (eg, voriconazole).

Troke P et al; Global Scedosporium Study Group. Treatment of scedosporiosis with voriconazole: clinical experience with 107 patients. Antimicrob Agents Chemother. 2008 May;52(5):1743–50. [PMID: 18212110]

Antifungal Therapy

Table 36–1 ssummarizes the major properties of currently available antifungal agents. Several different lipid-based amphotericin B formulations are used to treat systemic candidiasis, invasive aspergillosis and other disseminated mold infections, disseminated histoplasmosis, and cryptococcal meningitis. Their principal advantage appears to be substantially reduced nephrotoxicity, allowing administration of much higher doses. Because of their expense, use of these agents is often reserved for individuals in whom significant nephrotoxicity develops during amphotericin B therapy. Three agents of the echinocandin class, caspofungin acetate, anidulafungin, and micafungin sodium, are currently approved. The echinocandins have relatively few adverse effects and are useful for the treatment of invasive *Candida* infections. Caspofungin acetate is also approved for use in refractory cases of invasive aspergillosis. Voriconazole has excellent activity against a broad range of fungal pathogens and has been FDA approved for use in invasive *Aspergillus* cases, *Fusarium* and *Scedosporium* infections, *Candida* esophagitis, deep *Candida* infections, and candidemia. Posaconazole has good activity against a broad range of filamentous fungi, including some of the zygomycetes.

Cytokine therapy (such as with interferon-) and use of growth factors such as granulocyte macrophage-colony-stimulating factor (GM-CSF) (sargramostim or molgramostim) have been shown in animal models to increase clearance of fungi and result in better clinical outcomes and are being evaluated in human disease.

Table 36–1. Agents for systemic mycoses.

Drug	**Dosing**	**Renal Clearance?**	**CSF Penetration?**	**Toxicities**	**Spectrum of Activity**
Amphotericin B	0.3–1.5 mg/kg/d intravenously	No	Poor	Rigors, fever, azotemia, hypokalemia, hypomagnesemia, renal tubular	All major pathogens except *Scedosporium*

				acidosis, anemia	
Amphotericin B lipid complex	5 mg/kg/d intravenously	No	Poor	Fever, rigors, nausea, hypotension, anemia, azotemia, tachypnea	Same as amphotericin B, above
Liposomal amphotericin B	3–6 mg/kg/d intravenously	No	Poor	Fever, rigors, nausea, hypotension, azotemia, anemia, tachypnea, chest tightness	Same as amphotericin B, above
Anidulafungin	100 mg intravenous loading dose, followed by 50	< 1%	Poor	Diarrhea, hepatic enzyme elevations, histamine-mediated	Mucosal and invasive candidiasis

	mg/d intravenously in one dose			reactions	
Caspofungin acetate	70 mg intravenous loading dose, followed by 50 mg/d intravenously in one dose	< 50%[1]	Poor	Transient neutropenia; hepatic enzyme elevations when used with cyclosporine	Aspergillosis, mucosal and invasive candidiasis, empiric antifungal therapy in febrile neutropenia
Micafungin sodium	150 mg intravenously in one dose (treatment) 50 mg (prophylaxis)	No	Poor	Rash, rigors, headache, phlebitis	Mucosal and invasive candidiasis, prophylaxis in hematopoietic stem cell transplantation

Fluconazole	100–800 mg/d in one or two doses intravenously or orally	Yes	Yes	Nausea, rash, alopecia, headache, hepatic enzyme elevations	Mucosal candidiasis (including urinary tract), cryptococcosis, histoplasmosis, coccidioidomycosis
Flucytosine (5-FC)	100–150 mg/kg/d orally in four divided doses	Yes	Yes	Leukopenia,[2] rash, diarrhea, hepatitis, nausea, vomiting	Cryptococcosis,[3] candidiasis,[3] chromomycosis
Itraconazole	100–400 mg/d orally in one or two doses	No	Variable	Nausea, hypokalemia, edema, hypertension	Histoplasmosis, coccidioidomycosis, blastomycosis, paracoccidioidomycosis, mucosal

					candidiasis (except urinary), sporotrichosis, aspergillosis, chromomycosis
Ketoconazole	200–800 mg/d orally in one or two doses	No	Poor	Anorexia, nausea, suppression of testosterone and cortisol, rash, headache, hepatic enzyme elevations, hepatic failure	Nonmeningeal histoplasmosis and coccidioidomycosis, blastomycosis, paracoccidioidomycosis, mucosal candidiasis (except urinary)
Posaconazole	400–800 mg/d orally in one	No	Yes	Nausea, vomiting, abdominal pain, diarrhea,	Broad range of activity including zygomycosis

	or two doses			and headache	
Terbinafine	250 mg/d orally in one dose	Yes	Poor	Nausea, abdominal pain, taste disturbance, rash, diarrhea, and hepatic enzyme elevations	Dermatophytes, sporotrichosis
Voriconazole	200–400 mg/d orally in two doses or 12 mg/kg intravenously as loading dose for 2	Yes	Yes	Transient visual disturbances, rash, hepatic enzyme elevations[4]	All major pathogens except zygomycetes and sporotrichosis

	days followed by 6 mg/kg/d intravenously in two doses[5]				

[1] No dosage adjustment required for chronic kidney disease; dosage adjustment necessary with moderate to severe hepatic dysfunction.

[2] Use should be monitored with blood levels to prevent this or the dose adjusted according to creatinine clearance.

[3] In combination with amphotericin B.

[4] Administration with drugs that are metabolized by the cytochrome P450 system is contraindicated or requires careful monitoring.

[5] Because of polymorphisms affecting metabolism, some authorities advocate therapeutic drug monitoring in patients who are not responding to therapy.

Disorders due to Cold

The human body maintains a steady temperature through the balance of internal heat production and environmental heat loss. In extreme temperatures, the body's thermoregulation may fail. This results in the body's internal temperature moving toward the temperature of the external environment. Heat exchange between the body and environment occurs via four common processes: radiation, evaporation, conduction, and convection. Cold and heat tolerance vary considerably among individuals, depending on physiological and environmental factors.

Cold- and heat-related conditions may arise in any individual, regardless of sex, race, age, or underlying health status. Exposure to cold or heat may cause a wide spectrum of conditions. Factors that increase the likelihood of extreme temperature-related conditions include underlying cardiopulmonary, vascular, neurologic or musculoskeletal diseases; poor physical conditioning; nonacclimatization; advanced age; altered mental status;

poor tissue perfusion; inappropriate clothing; concurrent injury; poor peripheral vascular function; inadequate thermoregulation; systemic illness; pharmacologic effects of tobacco, alcohol, and drugs (ie, recreational drugs, sedatives, or drugs that affect sweating).

Cold Urticaria

Cold urticaria is a hypersensitivity to cold exposure (eg, wind, freezer compartments, water) resulting in histamine release. The hypersensitivity usually presents as localized redness, burning, pruritus, and urticaria in the exposed areas, or the response may progress to generalized systemic reaction, shock, and death. This condition may be familial or acquired. Familial cold urticaria is an autosomal dominant inflammatory disorder (including the Muckle-Wells syndrome), manifested as a burning sensation of the skin occurring about 30 minutes after exposure to cold. Acquired cold urticaria may be associated with medication (eg, griseofulvin) or with infection. Cold urticaria may occur secondarily to cryoglobulinemia or as a complication of syphilis. Most cases of acquired cold urticaria are idiopathic. For diagnosis, an ice cube is usually applied to the skin of the forearm for 4–5 minutes, then removed, and the area is observed for 10 minutes. As the skin rewarms, an urticarial wheal appears at the site that may be accompanied by itching. Second-generation antihistamines have been used as first-line treatment. Ebastine is also reported to safely and effectively prevent symptoms from acquired cold urticaria. Use of antileukotrienes in cold urticaria is anecdotal.

Raynaud Disease

See Chapter 20: Musculoskeletal & Immunologic Disorders.

Accidental Systemic Hypothermia

Essentials of Diagnosis

- Hypothermia is a reduction of core body temperature below 35 °C.
- An esophageal or rectal probe that measures as low as 25 °C is required; oral, axillary, and otic temperatures are inaccurate.
- Resuscitative measures must be continued until the core temperature is over 32 °C.

General Considerations

Systemic hypothermia is defined as core body temperature less than 35 °C. This may be primary (from exposure to prolonged ambient extremely low temperature) or secondary (due to thermoregulatory dysfunction). Primary and secondary hypothermia may be present at the same time. Hypothermia risk factors include malnutrition, hypothyroidism, adrenal insufficiency, hypopituitarism, diabetes mellitus, uremia, sedentary lifestyle, homelessness, inadequately heated housing, inadequate clothing, occupational or recreational exposure, prior cold weather injury, substance use or overdose, antipsychotic drug use, sepsis, infection, hypoglycemia, as well as the factors listed above. Heat loss occurs more rapidly with high wind velocity ("windchill factor"); water immersion or wet clothing; or direct contact with a cold surface (ie, stone, concrete, soil or the ground).

Accidental hypothermia may occur in the hospital setting due to prolonged postoperative hypothermia or administration of large amounts of refrigerated stored blood products (without rewarming), rapid infusion of intravenous fluids, or prolonged exposure of an undressed patient during resuscitation or procedures.

The human body generates internal heat through muscle activity (ie, shivering or increased physical exertion) and preserves heat loss via peripheral vasoconstriction. In prolonged or repetitive cold exposure, these thermoregulatory responses can become impaired; hypothermia ensues. Hypothermia diagnosis can be easily overlooked and delayed in a critically ill or injured patient. Hypothermia should be considered in any patient with prolonged exposure to ambient or cold environment, trauma, or inadequate clothing.

Systemic hypothermia alters physiologic function. This results in decreased respiratory drive, oxygen consumption, peripheral nerve conduction, gastrointestinal motility, myocardial repolarization, and coagulation cascade.

Clinical Findings

Symptoms and signs of hypothermia are typically nonspecific and markedly variable based on the patient's underlying health and circumstances of hypothermia. In mild cases with core temperature between 32 °C and 35 °C, symptoms include tachypnea, tachycardia, hypertension, shivering, impaired coordination, poor judgment, and apathy. With core temperature between 28 °C and 32 °C, the body slows down. Shivering stops; bradycardia, dilated pupils, slowed reflexes, cold diuresis, and confusion and lethargy ensue. Electrocardiogram (ECG) may reveal J wave or Osborn wave (positive deflection in the terminal portion of the QRS complex, most notable in leads II, V_5, and V_6) (Figure 37–1: ECG). Below 28 °C, the skin may appear blue or puffy; coma, apnea, loss of reflexes, asystole, or ventricular fibrillation may lead the clinician to assume that patient is dead. Prolonged hypothermia may lead to dysrhythmias and conduction abnormalities, acidemia, hyperkalemia, rhabdomyolysis, pulmonary edema, chronic kidney disease, pneumonia, pancreatitis, hypoglycemia or hyperglycemia, and coagulopathy. Death in systemic hypothermia is usually due to ventricular fibrillation, asystole, or chronic kidney disease.

Figure 37–1

Electrocardiogram shows leads II and V5 in a patient whose body temperature is 24 °C. Note the bradycardia and Osborn waves. These findings become more prominent as the body temperature lowers, and gradually resolve with rewarming. Osborn waves have an extra deflection at the end of the QRS complex. These are best seen in the inferior and lateral precordial leads.

Treatment

Resuscitation begins with assessment and support of airway, breathing and circulation, initiation of rewarming, and prevention of further heat loss. Rewarming is the initial, imperative treatment. All cold, wet clothing must be removed and replaced with warm, dry clothing. The patient should be evaluated for secondary causes of hypothermia, trauma, and peripheral cold injury. Rewarming methods are determined by the degree of hypothermia and the resources available.

During rewarming, continuous monitoring of temperature and other vital signs, cardiac rhythm, and blood sugar must be done. Common complications of rewarming occur as colder peripheral blood returns to central circulation. This may result in core temperature afterdrop, rewarming acidosis from shunting lactate into the circulation, rewarming shock from peripheral vasodilation and hypovolemia, ventricular fibrillation and other cardiac arrhythmias. Extreme caution must be taken when handling the hypothermic patient to avoid triggering arrhythmias. During the rewarming process, essential testing includes ECG, chest radiograph, arterial blood gases, and bedside glucose. Laboratory evaluation should assess for potential complications of lactic acidosis; rhabdomyolysis; electrolyte abnormalities; infection; and dysfunction of the pancreas, liver, kidneys, and coagulation. False laboratory values will occur if the blood sample is warmed to 37 °C for the testing. Antibiotics are not routinely given. Comatose patients have a high risk of aspiration pneumonia.

Passive and Active External Rewarming Methods

Patients with mild hypothermia (rectal temperature > 33 °C) who have been otherwise healthy usually respond well to passive and active external warming. **Passive external rewarming** involves removal of cold wet clothing and covering the patient with blankets to prevent further heat loss. The patient will rewarm due to the body's internal heat production through shivering and increased metabolism. **Active external rewarming** is highly effective and safe for mild hypothermia. This is a noninvasive method of applying external heat to the patient's skin. Examples include warm bedding, heated blankets, heat packs, and immersion into a 40 °C bath. Warm bath immersion limits the ability to monitor the patient or treat other coexisting conditions. Afterdrop can be lessened by active external rewarming of the trunk but not the extremities and by avoiding any muscle movement by the patient.

Active Internal (Core) Rewarming Methods

Active internal core rewarming methods are required for patients with core temperatures of < 33 °C. Patients with milder degrees of hypothermia may also benefit from these methods. Warm humidified oxygen (43–46 °C) is an easy, safe, and highly effective method. Warmed intravenous saline infusions (43 °C) should be used instead of lactated Ringer solution. Volume resuscitation is needed to prevent shock as vasodilation occurs during rewarming. Other methods (including warm solution lavage of the stomach, colon, thoracic cavity, peritoneum, or bladder; extracorporeal blood rewarming by cardiopulmonary, arteriovenous femorofemoral, or venovenous bypass; and hemodialysis) are based on the availability of equipment and skilled personnel. Esophageal rewarming tubes are used abroad and may soon become available in the United States. Endovascular warming devices are a less invasive alternative than extracorporeal methods but are not widely available in hospitals.

For patients with core temperature < 30 °C, treatment includes active rewarming, cardiopulmonary resuscitation (CPR), one shock attempt for dysrhythmia, and withholding of intravenous medications. Once the core temperature reaches 30 °C, cardiac medications can be given but at longer than standard intervals because metabolism is slowed and there is a risk of toxic accumulation as circulation is restored. Defibrillation may be performed as needed. Resuscitative efforts should be continued until the patient's core temperature increases to at least 32 °C.

Prognosis

Prognosis is directly related to the patient's underlying health and comorbidities, the severity of associated conditions, circumstances surrounding the hypothermia, and degree of metabolic acidosis. Prognosis is poor with low pH (6.6), elevated potassium (4.0 mEq/L), serious underlying condition, or treatment delay. If treated early, most otherwise healthy patients may survive moderate or severe hypothermia.

Hypothermia of the Extremities

Essentials of Diagnosis

- Cold-induced injuries should not be rubbed or massaged during rewarming.
- Rewarming of cold-induced injuries must be performed as soon as possible after there is no risk of refreezing.

Clinical Findings

Cold exposure of the extremities produces immediate localized vasoconstriction followed by generalized vasoconstriction. When the skin temperature falls to 25 °C, tissue demand for oxygen is greater than what is supplied by the slowed circulation: the area becomes cyanotic. At 15 °C, tissue damage occurs due to marked reduction in tissue metabolism and in oxyhemoglobin dissociation. This gives a deceptive pink, well-oxygenated appearance to the skin. Tissue death may result from ischemia and thromboses in the smaller vessels or by actual freezing. Freezing (frostbite) may occur when the skin temperature drops below –4 to –10 °C or at higher temperatures in the presence of wind, immobility, malnutrition, or vascular disease. Cold-induced injuries to the extremities (frostnip, chilbain, trench foot, and frostbite) range from mild to severe.

Prevention

"Keep warm, keep dry, and keep moving." Individuals should wear warm, dry clothing, preferably several layers, with a windproof outer garment. Arms, legs, fingers, and toes should be exercised to maintain circulation. Wet clothing, socks, and shoes should be replaced with dry ones. Extra socks, mittens, and insoles should always be carried in a pack during travel in cold or icy areas. Caution must be taken to avoid cramped positions; constrictive clothing; prolonged dependency of the feet; use of tobacco, alcohol, and sedative medications; and exposure to wet muddy ground and windy conditions.

Frostnip & Chilblain (Erythema Pernio)

Frostnip is a mild temporary form of cold-induced injury. The involved area has local paresthesias that completely resolve with passive external rewarming. Rewarming can be done by placing cold fingers in the armpits and, in the case of the toes or heels, by removing footwear, drying feet, rewarming, and covering with adequate dry socks or other protective footwear.

Chilblains or **erythema pernio** are inflammatory skin changes caused by exposure to cold without actual freezing of the tissues. These skin lesions may be red or purple, painful or pruritic, with burning or paresthesias; they may be associated with edema or blistering and aggravated by warmth. With continued exposure, ulcerative or hemorrhagic lesions may appear and progress to scarring, fibrosis, and atrophy. Chilblain lupus erythematosus, while clinically similar to ordinary chilblain, can be differentiated by an association with other lupus manifestations or by biopsy.

Treatment consists of elevating and passively externally rewarming the affected part. Caution must be taken to avoid rubbing or massaging injured tissues and to avoid applying ice or heat. The area must be protected from trauma and secondary infection. Prazosin, 1 mg orally daily, has been recommended for treatment and prevention of recurrence. Nifedipine (extended release 30–60 mg every 24 hours) has been recommended for pain.

Immersion Foot or Trench Foot

Immersion foot (or hand) is caused by prolonged immersion in cool or cold water or mud, usually less than 10 °C. Early symptoms include cold and anesthesia of the affected area (prehyperemic stage). This is followed by hot sensation, intense burning, shooting pains (hyperemic stage). With ongoing cold exposure, the affected part becomes pale or cyanotic with diminished pulsations due to vasospasm (posthyperemic stage). This may result in blistering, swelling, redness, ecchymoses, hemorrhage, necrosis, peripheral nerve injury, or gangrene and secondary complications such as lymphangitis, cellulitis, and thrombophlebitis. The condition was first described during trench warfare in World War I. Now, it is commonly seen in homeless patients.

Treatment is best instituted during the hyperemic stage. Treatment consists of air drying, protecting the extremities from trauma and secondary infection, and gradual rewarming by exposure to air at room temperature (not ice or heat). Caution must be taken to avoid massaging or moistening the skin and to avoid water immersion. Bed rest is required until all ulcers have healed. Affected parts are elevated to aid in removal of edema fluid, and pressure sites (eg, heels) are protected with pillows. Later treatment is the same as for Buerger disease (see Chapter 12: Blood Vessel & Lymphatic Disorders). Prevention involves properly fitting footwear, improved foot hygiene, and sock changes to keep feet clean and dry.

Frostbite

Frostbite is injury from tissue freezing and formation of ice crystals in the tissue. In mild cases, only the skin and subcutaneous tissues are involved; the symptoms are numbness, prickling, itching, and pallor. With increasing severity, deep frostbite involves deeper structures. The skin appears white or yellow, loses its elasticity, and becomes immobile. Edema, hemorrhagic blisters, necrosis, and gangrene may appear. This may cause paresthesias and stiffness.

Treatment

Immediate Treatment

Evaluate and treat the patient for associated systemic hypothermia and injury. Fluids and electrolytes should be monitored.

Rewarming

Rapid rewarming at temperatures slightly above body heat may significantly decrease tissue necrosis. If there is any possibility of refreezing, the frostbitten part should not be thawed, even if this might mean prolonged walking on frozen feet. Refreezing results in increased tissue necrosis. Rewarming is best accomplished by warm bath immersion. The frozen extremity is immersed for several minutes in a moving water bath heated to 40–42 °C until the distal tip of the part being thawed flushes. Water in this temperature range feels warm but not hot to the normal hand. Dry heat (eg, stove or open fire) is more difficult to regulate, increases likelihood of accidental burns and is not recommended. Thawing may cause tenderness and burning pain. Once the frozen part has thawed and returned to normal temperature (usually in about 30 minutes), discontinue external heat. Rewarming by exercise, rubbing, or friction is contraindicated in the early stage. The patient is kept at bed rest with the affected parts elevated and uncovered at room temperature. Casts, occlusive dressings, or bandages are not applied. A combination of ibuprofen, 200 mg four times daily, and aloe vera has been used to prevent dermal ischemia. Blisters should be left intact unless signs of infection supervene.

Anti-infective measures and wound care

Frostbite increases susceptibility to tetanus and infection. Tetanus prophylaxis must be considered. Infection risk may be reduced by aseptic wound care and protection of skin blebs from physical contact. Wounds should be kept open and allowed to dry before applying dressings. Nonadherent sterile gauze and fluffy dressing should be loosely applied to wounds and cushions used for all areas of pressure. Antibiotics should not be administered empirically. Systemic antibiotics are reserved for deep infections not responding to local wound care. Whirlpool therapy at 37–40 °C twice daily for 15–20 minutes for a period of 3 or more weeks helps cleanse the skin and debrides superficial sloughing tissue.

Medical and Surgical Treatment Options

Debridement and amputation should be considered only after it is established that the tissues are necrotic. Magnetic resonance imaging with angiography and technetium scintigraphy have been used to assess the extent of frostbite and to distinguish viable from nonviable tissue. Eschar formation without evidence of infection (even with black eschar formation) may be conservatively treated. The underlying skin may heal spontaneously with the eschar acting as a biologic dressing. Intra-arterial thrombolytic administration within 24 hours of exposure has resulted in improved tissue perfusion and has reduced amputation. Hyperbaric oxygen therapy has shown benefit in case reports.

Follow-Up Care

Gentle, progressive physical therapy to promote circulation should be instituted as tolerated.

Prognosis

Recovery from frostbite depends on the extent of initial tissue damage, the rewarming reperfusion injury, and the late sequelae (such as chronic kidney disease or postinjury infections) and underlying comorbidities. There may be increased susceptibility to discomfort and injury in the involved extremity upon reexposure to cold. Neuropathic sequelae such as pain, numbness, tingling, hyperhidrosis, and cold sensitivity of the extremities, and nerve conduction abnormalities may persist for many years after the cold injury.

Disorders due to Heat

Essentials of Diagnosis

- There is a spectrum of heat-related illnesses: heat cramps, heat exhaustion, heat syncope, and heat stroke.

General Considerations

Conduction (convection)—the direct transfer of heat from the skin to the surrounding air—occurs with diminishing efficiency as ambient temperature rises, especially above 37.2 °C, the point at which heat transfer reverses direction. At normal temperatures, evaporation accounts for approximately 20% of the body's heat loss, but at high temperatures it becomes the major mechanism for dissipation of heat; with vigorous exertion, sweat loss can be as much as 2.5 L/h. This mechanism diminishes as humidity rises.

Hyperthermia results from the body's inability to maintain normal internal temperature through heat loss. The body's heat source is a result of internal metabolic function and environmental conditions. Heat loss occurs through sweating and peripheral vasodilation. The common comorbidities and risk factors leading to heat-related conditions are listed in the chapter's introduction. Additional risk factors include inhibition of sweat production or evaporation, obesity, skin disorders (miliaria), reduced cutaneous blood flow, dehydration, hypotension, reduced cardiac output, and use of drugs that increase metabolism or muscle activity or impair sweating, prolonged seizures, and withdrawal syndromes. Medications that impair sweating include anticholinergics, antihistamines, phenothiazines, tricyclic antidepressants, monoamine oxidase inhibitors, and diuretics; reduced cutaneous blood flow results from use of vasoconstrictors and -adrenergic blocking agents; and dehydration results from use of alcohol. Illicit drugs—eg, phencyclidine, LSD, amphetamines, and cocaine—can cause increased muscle activity and thus generate increased body heat. The risk of heat disorder increases with age, impaired cognition, concurrent illness, body mass index, reduced physical fitness, duration of exertion, and insufficient acclimatization.

Prevention

Public education is necessary to improve prevention and early recognition of heat-related disorders. Individuals should take steps to reduce personal risk factors (ie, physical inactivity, obesity, tobacco and drug use) and to acclimatize to the hot environment. Acclimatization is achieved by scheduled regulated exposure to hot environments and by gradually increasing the duration of exposure and the workload until the body adjusts. Acclimatization is accompanied by increased plasma volume, cardiac output, and cardiac stroke volume and a slower heart rate, and sweat production of lower salt content in greater amounts at lower ambient temperatures. Proper acclimatization must be achieved before heavy physical exertion (ie, occupational or exercise) is performed in hot environments.

Medical evaluation and monitoring should be used to identify the individuals and the weather conditions that increase risk of heat-related disorders. Athletic events should be organized with attention to thermoregulation: the wet bulb globe temperature (WBGT) index should be monitored. Competition is not recommended when the WBGT exceeds 26–28 °C. Guidance regarding heat hazard is found in the National Weather Service's Heat Index that rates weather conditions based on humidity and temperature measurements (www.weather.gov/om/heat/index.shtml). The US Army provides guidance regarding activity levels according to WBGT levels (www.usariem.army.mil).

Those who are physically active in a hot environment should increase fluid consumption. Fluid consumption should include balanced electrolyte fluids and water. Water consumption alone may lead to electrolyte imbalance, particularly hyponatremia. It is not recommended to have salt tablets available for use without medical supervision. Close monitoring of fluid and electrolyte intake and early intervention are recommended in situations necessitating exertion or activity in hot environments. Exertional heat-related disorders are common in unconditioned participants in strenuous activities in hot humid conditions (ie, military drills, marathons, triathlon competitions, or exercise during heat waves).

Specific Syndromes due to Heat Exposure

Heat Syncope or Collapse

Sudden collapse or unconsciousness may result from volume depletion and cutaneous vasodilation with consequent systemic and cerebral hypotension. Exercise-associated postural hypotension is usually the cause of this: it may occur during or immediately following exercise. There is usually a history of prolonged vigorous physical activity. Typically, the skin is cool and moist, the pulse is weak, and the systolic blood pressure is low.

Treatment consists of rest and recumbency in a cool place and fluid and electrolyte rehydration by mouth (or intravenously if necessary).

Heat Cramps

Fluid and electrolyte depletion may result in slow, painful skeletal muscle contractions ("cramps") and severe muscle spasms lasting 1–3 minutes, usually of the muscles most heavily used. Cramping results from dilutional hyponatremia as sweat losses are replaced with water alone. The skin is moist and cool. The muscles are tender, hard and lumpy, and muscle twitching may be present. The patient is alert, with stable vital signs, and may be agitated and complaining of pain. The body temperature may be normal or slightly increased. There is almost always a history of vigorous activity just preceding the onset of symptoms. Laboratory evaluation may show low serum sodium, hemoconcentration, and elevated urea and creatinine.

The patient should be moved to a cool environment and given oral saline solution (4 tsp of salt per gallon of water) to replace both salt and water. *Oral salt tablets are not recommended.* The patient may have to rest for 1–3 days with continued dietary salt supplementation before returning to work or resuming strenuous activity in the heat.

Heat Exhaustion

Heat exhaustion results from prolonged strenuous activity with inadequate water or salt intake in a hot environment. It is characterized by dehydration, sodium depletion, or isotonic fluid loss with accompanying cardiovascular changes.

The diagnosis is based on prolonged symptoms and a rectal temperature over 37.8 °C, increased pulse (> 150% of the patient's normal) and moist skin. Symptoms are similar to those associated with heat syncope and heat cramps. Additional symptoms include nausea, vomiting, malaise, myalgias, hyperventilation, thirst, and weakness.

Central nervous system symptoms include headache, dizziness, fatigue, anxiety, paresthesias, impaired judgment, hysteria, and occasionally psychosis. Hyperventilation secondary to heat exhaustion can cause respiratory alkalosis; lactic acidosis may also occur due to poor tissue perfusion. Heat exhaustion may progress to heat stroke if sweating ceases and mental status declines.

Treatment consists of moving patient to a shaded, cool environment, providing adequate hydration (1–2 L over 2–4 hours), oral salt replenishment, and active cooling (ie, fans, cool packs) if necessary. Physiologic saline or isotonic glucose solution should be administered intravenously when oral administration is not appropriate. Indications for intravenous 3% (hypertonic) saline are the same as for the other causes of severe hyponatremia. At least 24 hours of rest and rehydration are recommended.

Heat Stroke

Heat stroke is a life-threatening medical emergency. The hallmarks of heat stroke are cerebral dysfunction with core temperature over 40 °C and absence of sweating. It presents in one of two forms: classic and exertional. **Classic heat stroke** occurs in patients with impaired thermoregulatory mechanisms; **exertional heat stroke** occurs in healthy persons undergoing strenuous exertion in a hot or humid environment. Persons at greatest risk are the very young, the elderly, the chronically debilitated, and those taking medications that interfere with heat-dissipating mechanisms (ie, anticholinergics, antihistamines, phenothiazines).

Heat stroke is associated with high morbidity and mortality from cerebral, cardiovascular, liver, or kidney damage. In a study of heat stroke patients, in-hospital mortality was 62.6%. Risk factors were identifiable within the first 24 hours of admission. A high Simplified Acute Physiology Score II, high body temperature, prolonged prothrombin time, use of vasoactive drugs within the first day in the intensive care unit (ICU), and an ICU without air conditioning all were associated with increased mortality.

Clinical Findings

Symptoms and Signs

Heat stroke may present with dizziness, weakness, emotional lability, nausea and vomiting, diarrhea, confusion, delirium, blurred vision, convulsions, collapse, and unconsciousness. The skin is hot, initially covered with perspiration; later it dries. The pulse is strong initially. Widened pulse pressure is present. Blood pressure may be slightly elevated at first, but hypotension develops later. Tachycardia and hyperventilation (with subsequent respiratory alkalosis) occur. The core temperature is usually over 40 °C. Exertional heat stroke may present with sudden collapse and loss of consciousness followed by irrational behavior. Anhidrosis may not be present. Twenty-five percent of heat stroke victims have prodromal symptoms for minutes to hours that may include dizziness, weakness, nausea, confusion, disorientation, drowsiness, and irrational behavior. Multiorgan dysfunction or injury is a common and serious complication.

Laboratory Findings

Laboratory evaluation may reveal dehydration; leukocytosis; elevated blood urea nitrogen (BUN); hyperuricemia; hemoconcentration; acid-base abnormalities (eg, lactic acidosis, respiratory alkalosis); decreased serum potassium, sodium, calcium, and phosphorus; thrombocytopenia, fibrinolysis, and coagulopathy; elevated creatine kinase (CK); elevated aminotransferase levels and liver dysfunction; and elevated cardiac markers. Urine is concentrated, with proteinuria, hematuria, tubular casts, and myoglobinuria. ECG findings may include ST–T changes consistent with myocardial ischemia. PCO_2 may be less than 20 mm Hg.

Treatment

Treatment is aimed at reducing the core temperature rapidly (within 1 hour) while supporting organ system function. Care must be taken to avoid shivering, which will increase internal heat production and inhibit effectiveness of cooling. Benzodiazepines may be used to suppress shivering. Evaporative cooling is a noninvasive, effective, quick and easy way to reduce temperature. The patient is undressed and the entire body sprayed with lukewarm water (20 °C) while large fans circulate the room air. The patient should be in the lateral recumbent position or supported in a hands-and-knees position to expose as maximum skin surface to the air. Alternatively, the use of cold wet sheets accompanied by fanning may be used. Inhalation of cool air or oxygen, and infusion of cool intravenous fluids are also effective.

Immersion in an ice-water bath (1–5 °C) is effective but impractical method due to its physical requirements and limitations to patient access and monitoring. Other cooling alternatives include hand and forearm immersion in cold water, localized ice or ice slush application (groin, axillas, neck), and iced gastric lavage. These are much less effective than evaporative cooling and usually less tolerated in the awake patient. Skin massage is recommended to prevent cutaneous vasoconstriction. Intravascular heat exchange catheter systems as well as hemodialysis using cold dialysate (30–35 °C) have been successful in reducing core temperature. Research suggests that brain cooling may lessen cerebrovascular injury from heat stroke. *Antipyretics (aspirin, acetaminophen) have no effect on environmentally* *induced hyperthermia and are contraindicated*. Treatment should be continued until the rectal temperature drops to 39 °C.

All patients with suspected heat stroke must be admitted to the hospital for close monitoring, including vital signs, temperature, and cardiac rhythm, and observation for 24 hours. The patient should also be monitored for potential complications of electrolyte abnormalities, acute kidney injury due to rhabdomyolysis, cardiac arrhythmias, coagulopathy, hepatic failure, acute respiratory distress syndrome (ARDS), hypoglycemia, seizures, and infection. Intravascular volume status should be assessed and managed. Hypovolemic and cardiogenic shock must be carefully distinguished, since either or both may occur. Central venous or pulmonary artery wedge pressure should be monitored. Five percent dextrose in half-normal or normal saline should be administered for fluid replacement. Oral or intravenous fluid administration must be provided to ensure a high urinary output (> 50 mL/h). Fluid output should be monitored through the use of an indwelling urinary catheter. Mannitol administration (0.25 mg/kg), and alkalinizing the urine (intravenous administration of 250 mL of 4% bicarbonate administration) may be needed.

Multiorgan dysfunction is the usual cause of heat stroke–related death, and it can be predicted by CK > 1000 units/L, metabolic acidosis, and elevated liver enzymes. Multiorgan dysfunction and inflammation may continue after temperature is normalized. Hypokalemia frequently accompanies heat stroke but may not appear until rehydration. Maintenance of extracellular hydration and electrolyte balance should reduce the risk of chronic kidney disease due to rhabdomyolysis.

Because sensitivity to high environmental temperature may persist for prolonged periods following an episode of heat stroke, immediate reexposure should be avoided.

Burns

The incidence and severity of burn injuries has been declining, with both deaths and acute hospitalizations attributable to burns down about 50%. Over three-fourths of burns involve less than 10% of total body surface area. Aggressive, early excision (24–72 hours postburn) of deeply burned tissues and skin grafting, early enteral feeding, and improved infection control have contributed to significantly lower mortality rates and shorter hospitalizations. Nonetheless, an estimated 1.25 million burn injuries and 51,000 acute hospitalizations of burn victims occur each year in the United States. Approximately 12,500 patients per year are admitted to dedicated burn units. Overall, 62% of all patients with burns seen in burn centers had minor burns that affected less than 10% of the total body surface area, and 6.5% of patients admitted had inhalation injury. Among burn patients, 70% were male and had a mean age of 33 years. Flame and scald burns accounted for 78% of injuries.

The first 48 hours of hemodynamic shifts offer the greatest opportunity to impact the survival of the multiply injured patient with burn injuries. Related injuries include smoke inhalation, fractures, and blast injuries. Subsequent problems include bacterial superinfection, sepsis, and multiorgan failure. Finally, scar contractures and disfigurement occur during the later stages of burn injury.

Classification

Burns are classified by extent, depth, patient age, and associated illness or injury. Accurate estimation of burn size and depth is important since this figure will quantify the parameters of resuscitation.

Extent

The "rule of nines" (Figure 37–2: illustration) is useful for rapidly assessing the extent of a burn. More detailed charts based on age are available when the patient reaches the burn unit. Therefore, it is important to view the entire patient after cleaning soot to make an accurate assessment, both initially and on subsequent examinations (see photograph). On average, the degree of burn is overestimated by 75% by referring doctors. This becomes important when air transport is instituted to a burn center for minor injuries. One rule of thumb is that the palm of the hand, open, constitutes 1% total body surface area in adults. Only second- and third-degree burns are included in calculating the total burn surface area, since first-degree burns usually do not represent significant injury in terms of prognosis or fluid and electrolyte management. However, first- or second-degree burns may convert to deeper burns, especially if treatment is delayed or bacterial colonization or superinfection occurs.

Figure 37–2

Estimation of body surface area in burns.

Fig.

Severely burned firefighter prior to initial debridement. Burns proved to be 40% TBSA. (Courtesy of B Moelleken.)

Depth

Judgment of depth of injury is difficult. The **first-degree burn** may be red or gray but will demonstrate excellent capillary refill. First-degree burns are not blistered initially. If the wound is blistered, this represents a partial-thickness injury to the dermis, or a **second-degree burn**. As the degree of burn is progressively deeper, there is a progressive loss of adnexal structures. Hairs can be easily extracted or are absent, sweat glands become less visible, and the skin appears smoother.

Deep second- and third-degree burns (see photograph) are treated in a similar fashion, since neither will heal appropriately without early debridement and grafting; the resultant skin is thin and scarred.

Fig.

Appearance of deep full-thickness burn on abdomen before and after extensive debridement. Patient was subsequently grafted successfully. (Courtesy of B Moelleken.)

The benefits of hyperbaric oxygen for treatment of acute burns remain unproven and anecdotal.

Survival After Burn Injury

The Prognostic Burn Index is the sum of the patient's age and percentage of full thickness or deep partial thickness burn. An additional 20% mortality is added if inhalation injury is present. Recently, patients with a 90–100% predicted mortality rate now have an estimated mortality rate of 50–70%. The Prognostic Burn Index is most useful at the extremes of age. Recent treatment advances have significantly reduced mortality rates, including early burn excision, skin substitute usage, and early enteral feeding. Transfer to a burn unit with its support staff is indicated when burns are large, when there are comorbidities, and when smaller burns occur in high risk areas. According to the 2005 Burn Repository Statistics, mortality rates among all burn victims have decreased from 6.2% in 1995 to 4.7% in 2005.

Associated Injuries or Illnesses

An injury commonly associated with burns is smoke inhalation (see Chapter 9: Pulmonary Disorders). Suspicion of inhalation injury is aroused when the nasal hairs are singed, the mechanism of burn involves closed spaces, the sputum is carbonaceous, or the carboxyhemoglobin level exceeds 5% in nonsmokers. This suspicion should lead the clinician to institute early intubation before airway edema occurs. The products of combustion, not heat, are responsible for lower airway injury. When carbon monoxide poisoning is suspected, pure oxygen is administered for 45 minutes. Early extubation is avoided for the first 48–72 hours since there is a risk of continued airway edema during the dynamic fluid shift period of early resuscitation. Electrical injury that causes burns may also produce cardiac arrhythmias that require immediate attention. Pancreatitis occurs in severe burns. Prior alcohol exposure may exacerbate the pulmonary components of burn injury.

Toxic epidermal necrolysis (TEN) occasionally occurs following sulfonamide or phenytoin administration (see Chapter 6: Dermatologic Disorders). If TEN is severe, patients are best transferred to a burn unit and treated as having severe burn injury. Corticosteroid therapy should be avoided.

Systemic Reactions to Burn Injury

The actual burn injury is only the incipient event in a cascade of deleterious local tissue and systemic inflammatory reactions leading to multiorgan system failure in the severely burned patient. When burns greater than approximately 20% of total body surface area are present, systemic metabolic alterations occur and require intensive support. The inflammatory cascade can result in shock.

Initial Management

Airway

The practitioner or emergency medical technician should proceed as with any other trauma using standard Advanced Trauma Life Support (ATLS) guidelines. The priorities are first to establish an airway, recognizing the frequent necessity to intubate a patient who may appear to be breathing normally but who has sustained an inhalation injury; next, to evaluate the cervical spine and head injuries; and finally, to stabilize fractures. Fluid resuscitation by the Parkland formula (see below) may be instituted simultaneously with initial resuscitation. Endotracheal intubation or tracheotomy should be considered for major burn cases regardless of the area of the body involved, because as fluid resuscitation proceeds generalized edema develops, including edema of the soft tissues of the upper airway and perhaps the lungs as well. Chest radiographs are typically normal initially but may develop an ARDS picture in 24–48 hours with severe inhalation injury. Supplemental oxygen should be administered. Inhalation injuries should be monitored with serial blood gas determination and bronchoscopy. The use of corticosteroids or routine use of antibiotic therapy is not indicated.

Vascular Access

A thorough examination is performed to assess the extent of burn and associated injuries. Large bore venous catheter access is established. Subclavian lines are avoided in the emergency setting because of the risk of pneumothorax and subclavian vein laceration when such a line is placed in a volume-depleted patient. Femoral lines provide good temporary access during resuscitation. *Venous access catheters placed in the emergency department should be changed within 24 hours because of the high risk of nonsterile placement.* An arterial line is useful for monitoring mean arterial pressure and for drawing blood in critically ill patients.

Fluid Resuscitation

Crystalloids

Generalized capillary leak results from burn injury over more than 20% of total body surface area. This often necessitates replacement of a large volume of fluid.

There are many guidelines for fluid resuscitation. The

Parkland formula relies on the use of lactated Ringer injection. The fluid requirement in the first 24 hours is estimated as 4 mL/kg body weight per percent of body surface area burned. Half the calculated fluid is given in the first 8-hour period. The remaining fluid, divided into two equal parts, is delivered over the next 16 hours. An extremely large volume of fluid may be required. For example, an injury over 40% of the total body surface area in a 70-kg victim may require 11.2 L in the first 24 hours [4 mL x 40(%) x 70 (kg) = 11,200 mL]. The first 8-hour period is measured from the hour of injury. These guidelines may be inadequate, since crystalloid solutions alone may be insufficient to restore cardiac preload during the period of burn shock.

Deep electrical burns and inhalation injury increase the fluid requirement. Adequacy of resuscitation is determined by clinical parameters, including urinary output and specific gravity, blood pressure, pulse, temperature, and central venous pressure. The need for fluid replacement of more than 150% of calculated values indicates possible unrecognized injury, possible comorbidities, and a worse prognosis and may indicate the need for a Swan-Ganz catheter to assist in management.

Colloids

Overly aggressive crystalloid administration must be avoided in patients with pulmonary injury, since significant pulmonary edema can develop in patients with normal pulmonary capillary wedge and central venous pressures. In addition, routine colloid administration, previously commonplace, is no longer warranted in routine burn resuscitation in view of its deleterious effect on glomerular filtration and its association with pulmonary edema.

Monitoring Fluid Resuscitation

A Foley catheter is essential for monitoring urinary output. Diuretics have no role in this phase of patient management unless fluid overload has occurred or mannitol diuresis is performed in the case of rhabdomyolysis.

Abdominal Compartment Syndrome

Abdominal compartment syndrome is emerging as a potentially lethal condition in severely burned patients, even if abdominal decompression is performed. Markedly increased intra-abdominal pressures can cause pulmonary damage and multisystem organ failure. Only 40% of patients with this complication survive. Bladder pressures over 30 mm Hg establish the diagnosis in at-risk patients. Surgical abdominal decompression may be indicated to improve ventilation and oxygen delivery, but even after this, surgery survival remains low.

Escharotomy

As edema fluid accumulates, ischemia may develop under any constricting eschar of an extremity, neck, or trunk if the full-thickness burn is circumferential. Escharotomy incisions through the anesthetic eschar can save life and limb and can be performed in the emergency department or operating room.

Fasciotomy in Electrical Burns or Crush Injuries

When high-voltage electrical injury occurs, extensive deep tissue necrosis should be suspected. Deep tissue necrosis leads to profound tissue swelling. Because deep tissue compartments in the arms and legs are contained by unyielding fascia, these compartments must be opened by surgical fasciotomy to prevent further soft tissue, vascular, and nerve death.

Electrical burn injuries remain the most devastating and underrecognized burn injuries, causing amputations (often because of unrecognized compartment syndromes) and acute kidney injury, resulting in part from rhabdomyolysis.

The Burn Wound

Minor burn wounds should be debrided at bedside to determine the depth of the burn and then thoroughly cleansed. Thereafter, the wound should be debrided daily and dressed with a topical antibiotic such as silver sulfadiazine (Silvadene) or bacitracin ointment. Patient compliance and adequate pain treatment is essential for successful outpatient treatment. The wound should be reevaluated by the treating surgeon if possible within 72 hours to evaluate for signs of infection.

Biobrane and Tegaderm should be reserved for clean scald burns. Acute burns caused by hydrofluoric acid should be treated by water rinsing followed by application of topical calcium. Treatment of the burn wound is based on protecting the wound from desiccation and avoiding further injury of those burned areas that will spontaneously reepithelialize in 7–10 days by application of topical antibiotic such as silver sulfadiazine (Silvadene). It is painless, easy to apply, and effective against most strains of *Pseudomonas*. For severely burned patients, Integra, a temporary skin substitute that can create a thin neodermis, may provide temporary coverage (and may even reduce hospitalization) but it is very expensive. Regular and thorough cleansing of burned areas is a critically important intervention in burn units. Early excision and grafting of burned areas may be performed as soon as 24 hours after burn injury or when the patient can hemodynamically tolerate the excision and grafting procedure. Meticulous prevention of seromas, hypergranulation tissue formation, and malnutrition all decrease time to complete wound healing in skin-grafted

patients.

Systemic infection remains a leading cause of morbidity among patients with major burn injuries, with nearly all severely burned patients having one or more septicemic episodes during the hospital course. Antibiotic usage should be targeted to specific organisms obtained by culture. Healthcare-associated infections are increasingly common. Obtaining pharmacologic expertise is useful in choosing appropriate antibiotic therapy, interpreting varying drug levels, and assessing drug-drug interactions. Coagulase-negative staphylococci (63%) and *Staphylococcus aureus* (20%) are commonly cultured from burn wounds. Methicillin-resistant *S aureus*, *vancomycin-resistant Enterococcus*, and *Pseudomonas aeruginosa* are also commonly cultured but usually later in the hospital course. *P aeruginosa* infections are associated with the highest mortality rate (33% vs 9% in nonpseudomonal infections), with aminoglycoside-resistant *Pseudomonas* infections particularly morbid. Routine use of blood culture in the severely burned population is indicated to elucidate systemic blood infections that do not manifest these clinical predictors of sepsis.

Wound Closure

The goal of therapy after fluid resuscitation is rapid and stable closure of the wound. Wounds that will not heal spontaneously in 7–10 days (ie, deep second-degree or third-degree burns) are best treated by excision and autograft (see photograph); otherwise, granulation and infection may develop (see photograph), and the quality of the skin in regenerated deep partial thickness burns is marginal because of the very thin dermis that emerges.

Cultured allogeneic keratinocyte grafts can provide rapid early coverage for superficial burn injuries. With severe burns, skin substitution with such cultured grafts can be lifesaving. However, although the replaced dermis does have nearly normal histologic dermal elements, there are no adnexal structures present and very few, if any, elastic fibers. Intraoperative use of topical fibrin sealants may reduce blood loss, improve cosmetic results, and improve postoperative graft adherence.

Patient Support

Burn patients require extensive support. An attempt must be made to maintain normal core body temperature (by maintaining environmental temperature at or above 30 °C) in patients with burns over more than 20% of total body surface area, since the hypermetabolic state of burns is exacerbated by subnormal temperatures. Respiratory injury, sepsis, and multiorgan failure are common. Enteral feedings may be started once the ileus of the resuscitation period has resolved, usually the day after the injury. There is often a markedly increased metabolic rate after burn injury, due in large part to whole body synthesis and increased fatty acid substrate cycles. If the patient does not tolerate low-residue tube feedings, total parenteral nutrition should be started without delay through a central venous catheter. Contrary to conventional teachings, data indicate that most patients can be fed adequately with energy equal to 100% to 120% of estimated basal energy expenditure (BEE). A useful guide is to provide 25 kcal/kg body weight plus 40 kcal per percent of burn surface area. Early aggressive enteral nutrition reduces infections, noninfectious complications, length of hospital stay, impaired healing, and mortality. Anticatabolic treatments such as -blockade, growth hormone, insulin, oxandrolone, and synthetic testosterone have been advocated. Melatonin, which appears to possess multifaceted antioxidant properties, may reduce proinflammatory cytokines and have beneficial chronobiotic effects in severely burned patients.

Careful control of the postinjury blood glucose has been associated with improved hepatic function and better survival after severe burns. Occasionally, ARDS or respiratory failure unresponsive to maximal ventilatory support may develop in burn patients. In addition, the incidence of venous thromboembolism in the lower extremities is high among burn patients. Duplex ultrasonography is the best method for identifying venous thromboembolism.

Prevention of long-term scars remains a formidable problem in seriously burned patients. The V-beam pulsed dye laser and intense pulsed light are emerging as adjunctive treatments to the usual regimen of corticosteroid injections, silicone patches, compression, and scar revision. Permanent sequelae can be avoided by prevention of infection, early aggressive rehabilitation, compressive garments, and early psychological support. Facial transplantation has become a controversial but potential treatment for those patients with devastating unreconstructable facial burns.

Complex microsurgical reconstructions, including prefabricated reconstructive flaps, now benefit severely burned patients with injuries to neck, hand, and arm (see photograph).

Electrical Injury

Essentials of Diagnosis

- Extent of injury is determined by the type, amount, duration, and pathway of electrical current.
- Resuscitation must be attempted on an electrical injury victim before assuming the patient is dead; clinical findings are unreliable.
- Skin findings may be misleading, and not indicative of the degree of deeper injury.

General Considerations

Electricity-induced injury occurs by exposure to electrical current of low voltage, high voltage, or lightning. Current passing through skeletal muscle can cause muscle necrosis and contractions severe enough to result in bone fracture. Current traversing peripheral nerves can cause acute or delayed neuropathy. Delayed effects can include damage to the eye, spinal cord, peripheral nerves, bone, kidneys, and gastrointestinal tract. If the current passes through the heart or brainstem, death may be immediate due to ventricular fibrillation, asystole, or apnea. Direct current (DC) is unidirectional electrical flow. It is more likely to cause a single intense muscle contraction and asystole. Alternating current (AC) is bidirectional electrical flow that reverses direction in a sine wave pattern forward to backward direction. This may cause muscle tetany, which prolongs the duration and amount of current exposure. If AC current passes through the thoracic area, it may lead to respiratory arrest or ventricular fibrillation. AC current of 25–300 Hz, low voltages (< 220 Hz) tend to produce ventricular fibrillation; high voltages (> 1000 Hz) cause respiratory failure; intermediate voltages (220–1000 Hz) cause both. More than 100 mA of domestic house AC of 110 volts at 60 Hz is, accordingly, dangerous to the heart, since it can cause ventricular fibrillation. Low voltage is less than 1000 volts, and high voltage is more than 1000 volts. High voltage is most often related to occupational exposure and associated with higher morbidity and mortality. Fatal injury and significant damage may also occur with exposure to low voltage of household AC current. Lightning differs from high-voltage electrical shock in that lightning is massive high voltage (millions of volts) lasting a very brief duration (a small fraction of a second).

Electricity causes damage by various means: direct tissue damage, muscle tetany, direct thermal injury and coagulation necrosis, and trauma from associated falls or violent muscle contractions. The degree of injury depends on the following factors: current type, voltage, and pathway; duration of exposure; tissue resistance; associated trauma; and comorbidities. Tissue resistance varies through the body. Nerve cells are the most vulnerable and bone is the most resistant to electrical current. Skin resistance depends on thickness and condition of skin.

Clinical Findings

The type and degree of injury is highly dependent on the current pathway. Symptoms and signs may range from tingling, superficial skin burns, and myalgias to paralysis, massive tissue damage, or death. Skin damage does not correlate with the degree of injury. Not all electrical injuries cause skin damage; only very minor skin damage may be present with massive internal injuries. Electrical burns are of three distinct types: flash (arcing) burns, flame (clothing) burns, and the direct heating effect of tissues by the electrical current. The latter lesions are usually sharply demarcated, round or oval, painless yellow-brown areas (Joule burn) with inflammatory reaction. Significant subcutaneous damage can be accompanied by little skin injury, particularly with larger skin surface area electrical contact.

A victim of electrical current injury may appear dead due to dysrhythmia, respiratory arrest, or autonomic dysfunction resulting in pupils that are fixed, dilated, or asymmetric. Resuscitation must be initiated on all victims of electrical injury since clinical findings are deceptive.

Complications

Complications include seizures, paralysis, headache, dysrhythmias, pneumothorax, tissue edema and necrosis, compartment syndrome, fractures from falls or muscle contractions, rhabdomyolysis, acute kidney injury, hypovolemia from third spacing, ruptured ear drums, and acute or delayed cataract formation.

Treatment

Emergency Measures

The victim must be separated from the electrical current prior to initiation of CPR or other treatment. The rescuer must be protected. Turn off the power, sever the wire with a dry wooden-handled ax, make a proper ground to divert the current, or separate the victim using nonconductive implements such as dry clothing. Resuscitation must then be initiated since clinical findings of death are unreliable.

Hospital Measures

The initial assessment involves airway, breathing, and circulation followed by trauma protocol. Fluid resuscitation is important to maintain adequate urinary output (0.5 mL/kg/h if no myoglobinuria is present, 1.0 mL/kg/h if myoglobinuria is present). Initial evaluation includes cardiac monitoring and ECG, complete blood count, electrolytes, renal function tests, liver biochemical tests, urinalysis, urine myoglobin, serum CK, and CK-MB. Victims must be evaluated for hidden injury (eg, ophthalmic, otologic, muscular, compartment syndromes), organ injury (myocardium, liver, kidney, pancreas), blunt trauma, dehydration, skin burns, hypertension, posttraumatic stress, acid-base disturbances, and neurologic damage.

Prognosis

Prognosis depends on the degree and location of electrical injury, initial damage, and complications. Complications may occur in almost any part of the body but most commonly include sepsis; gangrene requiring limb amputation; or neurologic, cardiac, cognitive, or psychiatric dysfunction. Psychiatric support may be necessary following lightning or severe electroshock exposures.

When to Refer

Fasciotomy may be needed for compartment syndrome. Research suggests some benefit from microvascular reconstruction.

When to Admit

Indications for hospitalization include arrhythmia or ECG changes; high voltage exposure; large burn; neurologic, pulmonary, or cardiac symptoms; suspicion of significant deep tissue or organ damage; transthoracic current pathway; history of cardiac disease; and need for surgery.

Radiation Exposure

Radiation exposures occur from both nonionizing and ionizing radiation sources. Nonionizing radiation is low energy, resulting in injuries related to local thermal damage (ie, microwave and radiowave). Ionizing radiation is high energy, causing cellular disruption, DNA damage, and mutations. Ionizing radiation is either electromagnetic (ie, x-rays and gamma rays) or particulate, (ie, alpha or beta particles, neutrons, and protons).

Exposure to radiation may occur from environmental, occupational, medical care, accidental, or intentional (ie, terrorism) exposure. The extent of damage due to radiation exposure depends on the type, quantity, and duration of radiation exposure, the organs exposed, the degree of disruption to DNA, metabolic and cellular function, and the age and underlying condition of the victim.

In 2008, the International Commission on Radiological Protection (ICRP) issued new recommendations for radiologic protection, justification for radiation use, and optimization of protection, and application of dose limits. ICRP uses the term "tissue reaction" to describe the biologic effects of radiation exposure.

The National Committee on Radiation Protection has established the maximum permissible radiation exposure for occupationally exposed workers over age 18 as 1 mSv (0.1 rem)* per week for the whole body (but not to exceed 50 mSv per year) and 15 mSv per week for the hands. (For purposes of comparison, routine chest radiographs deliver from 1 mSv to 2 mSv.) The US Food and Drug Administration has recommended 1 Gy as a threshold for skin-absorbed dose from medical fluoroscopy.

*In radiation terminology, a rad is the unit of absorbed dose and a rem is the unit of any radiation dose to body tissue in terms of its estimated biologic effect. Roentgen ® refers to the amount of radiation dose delivered to the body. For x-ray or gamma ray radiation, rems, rads, and roentgens are virtually the same. For particulate radiation from radioactive materials, these terms may differ greatly (eg, for neutrons, 1 rad equals 10 rems). In the Système International (SI) nomenclature, the rad has been replaced by the gray (Gy), and 1 rad equals 0.01 Gy = 1 cGy. The SI replacement for the rem is the Sievert (Sv), and 1 rem equals 0.01 Sv.

In **acute radiation exposure**, medical care includes close monitoring of the gastrointestinal, cutaneous, hematologic, and cerebrovascular symptoms and signs from initial exposure and over time. Radiation dose may be estimated by the timing of symptom onset and severity of symptoms, (particularly nausea and vomiting), decrease in absolute lymphocyte count over hours and days after exposure, and chromosomal abnormalities in circulating lymphocytes.

Radiation exposure results in early and delayed effects. Early effects involve damage of the rapidly dividing cells (ie, the mucosa, skin, and bone marrow). Delayed effects include malignancy, reproduction abnormalities, liver, kidney, and central nervous system and immune system dysfunction. The short-term and long-term outcomes of Chernobyl, Hiroshima, and Nagasaki illustrate these various radiation effects.

Immediate & Delayed Effects of Radiation Exposure On Normal Tissues

Clinical Findings

Injury to Superficial Structures

Radiation exposure to the skin and mucous membranes may cause erythema, epilation, destruction of fingernails, or epidermolysis, and burns that appear similar to thermal burns usually have a slower onset and course. Chronic damage includes skin scarring, atrophy, telangiectasis, and xerostomia. Radiation effects on the eyes include cataracts, dry eye syndrome, and retinopathy.

Injury to Deep Structures

Hematopoietic system

Injury to the bone marrow may vary from transient decreases to complete destruction of blood elements. Lymphocytes are most sensitive, followed by polymorphonuclear leukocytes; erythrocytes are the least sensitive. Hematopoietic effects consisting of anemia, thrombocytopenia, and bone marrow suppression can occur 1–3 weeks after radiation exposures exceeding 100 cGy. Bone marrow failure is the main cause of death within the first few months following exposure.

Nervous system

The brain and spinal cord are much more sensitive than the peripheral nerves to the acute and delayed effects of radiation. Effects include neuropathy, myelopathy, and cerebral injury. Radiofrequency fields emitted by mobile telephones have been linked to the formation of benign and malignant brain tumors.

Cardiovascular system

Ionizing radiation damages the heart and coronary arteries. Smaller vessels (the capillaries and arterioles) are more susceptible to damage than larger blood vessels. Delayed effects from radiation include obliterative endarteritis; coronary artery disease; pericarditis with effusion; or constrictive pericarditis, which may occur months or years later. Myocarditis is less common.

Pulmonary system

High or repeated moderate doses of radiation may cause pneumonitis or pulmonary fibrosis, which is often delayed for weeks or months.

Gastrointestinal system

Mucositis and mucosal edema may occur within hours or days after exposure. Symptoms include odynophagia, anorexia, nausea, vomiting, dehydration, and weakness. High doses of radiation inhibit gastric secretion and cause inflammation and ulceration of the bowels. Hepatitis, liver dysfunction, and intestinal stenosis may occur as delayed effects.

Genitourinary and reproductive systems

Genitourinary radiation effects are dose-dependent, varying from transient decrease in fertility to permanent sterility, chromosomal aberrations, fetal damage, or demise. Nephritis and kidney dysfunction may occur as immediate or delayed effects. In men, small single doses of radiation (200–300 cGy) cause temporary aspermatogenesis, and larger doses (600–800 cGy) may cause permanent sterility. In women, single doses of 200 cGy may cause temporary cessation of menses, and 500–800 cGy may cause permanent castration. Moderate to heavy irradiation of the embryo results in injury to the fetus (eg, mental retardation) or in embryonic death and spontaneous abortion. Microcephaly and other congenital abnormalities may occur in children exposed in utero, especially if the fetus was exposed during early pregnancy.

Endocrine system

The endocrine system is relatively resistant to low or moderate doses of radiation; thyroid, pituitary, pancreas, adrenals, and bladder maintain relatively normal function, and parathyroid glands are especially resistant. Delayed effects of exposure include thyroid dysfunction.

Systemic Reaction (Radiation Sickness)

The basic mechanisms of radiation sickness are not known. Symptoms include anorexia, nausea, vomiting, weakness, exhaustion, lassitude and, in some cases prostration; these symptoms may occur singly or in combination. Dehydration, anemia, and infection may follow.

Prevention

Persons handling radiation sources must minimize exposure to radiation by recognizing the importance of time, distance, and shielding. Occupational safety policies and procedures must be followed for frequent equipment maintenance, employee education, and training. This will reduce occupational risk of radiation exposure and improve the emergency response to accidental exposure. Areas housing x-ray and nuclear materials must be properly shielded. X-ray equipment should be periodically checked for reliability of output, and proper filters should be used. When feasible, it is advisable to shield the gonads, especially of young persons. Fluoroscopic procedures should be performed as rapidly as possible using an optimal combination of beam characteristics and filtration, and the minimum beam size required by the examination. Special protective clothing may be necessary to protect against contamination with radioisotopes. In the event of accidental contamination, all clothing should be removed and the body vigorously bathed with soap and water. This should be followed by careful instrument (Geiger counter) check to localize the ionizing radiation.

Accidental or Intentional Radiation Exposure

There is an increase in likelihood of accidental or intentional radiation exposure due to the increased use of radiation equipment, radioactive materials, and threat of nuclear terrorism. Prehospital and hospital disaster plans are required for optimal management of radiation exposure. This includes the triage, decontamination, emergency management, and disposition of victims and contaminants. The Radiation Assistance Center (1-865-576-1005) provides 24-hour access to expert information regarding medical and safety aspects of ionizing radiation exposures and incidents as well as detailed guidance regarding decontamination, diagnosis, treatment, and isotope-specific postexposure prophylaxis. The Centers for Disease Control and Prevention "Radiation Emergency" website (www.bt.cdc.gov/radiation/index.asp) is also helpful.

Treatment

Treatment is focused on decontamination, symptomatic relief, supportive care, and psychosocial support. Specific treatment options focus on the dose, route, and effects of exposure. Options include administration of fluids and electrolytes, blood product transfusion, antimicrobials, prophylaxis against malignancy, blood stem cell transplantation, and bone marrow transplantation.

For some radioisotopes (eg, iodine), chelation, blocking, or dilution therapy may be indicated. Recombinant hematopoietic colony stimulating factors/cytokines (filgrastim, sargramostim, or pegfilgrastim) have been effective in accelerating hematopoietic recovery. Investigational drugs are being tested as prophylaxis for acute radiation syndrome.

Prognosis

Prognosis is determined by the radiation dose, duration, and frequency as well as by the underlying condition of the victim. Approximate dose of exposure correlates with the early onset and severity of symptoms (ie, nausea, vomiting, anorexia, abdominal pain, bloody diarrhea, weight loss) and laboratory findings, particularly the decline in lymphocyte count on the complete blood count. Death is usually due to hematopoietic failure (ie, hemorrhage, anemia, and immunosuppression), gastrointestinal mucosal damage, central nervous system damage, widespread vascular injury, or secondary infection. The acute radiation syndrome may be dominated by central nervous system, gastrointestinal, or hematologic manifestations depending on dose and survival. Fatigue, weakness, and anorexia can occur following exposures exceeding 50 cGy. Exposure to 400–600 cGy may be fatal within 60 days. Whole body exposure levels of 1000–3000 cGy destroy gastrointestinal mucosa; this leads to toxemia and death within 2 weeks. Total body doses above 3000 cGy cause widespread vascular damage, cerebral anoxia, hypotensive shock, and death within 48 hours.

The International Agency for Research on Cancer (IARC) reviews the increasing evidence linking radiation exposure to increased cancer risk. Carcinogenesis is related to the total dose, duration, frequency of exposure and to the susceptibility of the victim. Relatively low dose exposures (< 0.2 Gy) are linked to leukemia and cancers of the skin, breast, lung, and thyroid. High-dose exposure is associated with an increased risk of lung cancer. Association of ionizing radiation with several other cancers has been reported but not well quantified (salivary glands, skin, stomach, colon, bladder, ovary, and central nervous system). There are age-related sensitivities to radiation; prenatal and younger age victims are more susceptible to carcinogenesis. Prenatal irradiation and early childhood exposure increase the risk of childhood cancer (eg, the Chernobyl accident led to an increase in childhood thyroid cancer).

When to Admit

Most patients with significant ionizing radiation exposure require admission for close monitoring and care.

Near Drowning

Essentials of Diagnosis

- The first requirement of rescue is immediate CPR.
- Clinical manifestations are hypoxemia, pulmonary edema, and hypoventilation.

General Considerations

Near drowning describes a submersion event leading to injury. Submersion injury may result in aspiration, laryngospasm, hypoxemia, and acidemia. Drowning describes submersion resulting in death. The asphyxia of drowning is usually due to aspiration of fluid, but it may result from airway obstruction caused by laryngeal spasm while the victim is gasping under water. The rapid sequence of events after submersion—hypoxemia, laryngospasm, fluid aspiration, ineffective circulation, brain injury, and brain death—may take place within 5–10 minutes. This sequence may be delayed for longer periods if the victim, especially a child, has been submerged in very cold water or if the victim has ingested significant amounts of barbiturates. About 10% of victims develop laryngospasm after the first gulp and never aspirate water ("dry drowning"). Immersion in cold water can also cause a rapid fall in the victim's core temperature, so that systemic hypothermia and death may occur before actual drowning. "Wet" drowning is due to aspiration of fluid or foreign material. "Dry" drowning is due to laryngospasm or airway obstruction. The primary effect is hypoxemia due to perfusion of poorly ventilated alveoli, intrapulmonary shunting, and decreased compliance.

Conditions that increase risk of submersion injury include the following: (1) use of alcohol or other drugs (a contributing factor in an estimated 25% of adult drownings), (2) extreme fatigue, (3) poor physical health, (4) hyperventilation, (5) sudden acute illness (eg, hypoglycemia, seizure, dysrhythmia, myocardial infarction), (6) acute brain or spinal cord injury (or both), (7) venomous stings, bites, or injury in the water, and (8) decompression sickness.

Spontaneous return of consciousness often occurs in otherwise healthy individuals when submersion is very brief. Many other patients respond promptly to immediate ventilation. Other patients, with more severe degrees of near drowning, may have frank respiratory failure, pulmonary edema, shock, anoxic encephalopathy, cerebral edema, and cardiac arrest. A patient may be deceptively asymptomatic during the initial recovery period only to deteriorate or die as a result of acute respiratory failure within the following 12–24 hours.

Clinical Findings

Symptoms and Signs

The patient's appearance may vary from asymptomatic, to abnormal vital signs, anxiety, dyspnea, cough, wheezing, trismus, cyanosis, chest pain, dysrhythmia, hypotension, vomiting, diarrhea, headache, altered level of consciousness, neurologic deficit, and apnea. A pink froth from the mouth and nose indicates pulmonary edema. With cold water or prolonged submersion, hypothermia is likely.

Laboratory Findings

Arterial blood gas results are helpful in determining the degree of injury since initial clinical findings may appear benign. Pao_2 is usually decreased; $Paco_2$ may be increased or decreased; pH is decreased. Bedside blood sugar must be checked rapidly. Other testing is based on clinical scenario and may include kidney function, electrolytes, urinalysis, blood count, lactate, cardiac markers, coagulation studies, and alcohol and toxicology levels. Metabolic acidosis is common. Urinalysis shows proteinuria, hemoglobinuria, and acetonuria. Leukocytosis is usually present.

Prevention

Prevention is multi-faceted. Physical barriers (ie, fences) should be placed around pools and other accessible bodies of water. Safety flotation devices and rescue supplies must be immediately available. Use of alcohol or sedative drugs must be avoided during swimming, boating, or other water-based activities. There must be close supervision of those who cannot swim, and personal flotation devices must be worn when boating or water skiing. Swimming lessons, water safety, and basic life support education is necessary for anyone involved in water-based activities.

Treatment

First Aid

The first requirement of rescue is immediate basic life support (BLS) treatment and CPR. At the scene, immediate measures to combat hypoxemia are critical to improve outcome. BLS care includes sustained ventilation, oxygenation, and circulatory support. Hypothermia and cervical spine injury should always be suspected.

1. Standard BLS is initiated. CPR is provided if pulse and respirations are absent.
2. Rescuer should not attempt to drain water from the victim's lungs. The Heimlich maneuver (subdiaphragmatic pressure) should be used only if foreign material airway obstruction is suspected. The cervical spine must be immobilized if neck injury is possible.
3. Resuscitation and BLS efforts must be continued until core temperature reaches 32 °C even for seemingly "hopeless" patients. Complete recovery has been reported after prolonged resuscitation of hypothermic patients.

Subsequent Management

Careful inpatient monitoring of the patient's condition must occur for 24 hours following near drowning. This includes continuous monitoring of cardiorespiratory and neurologic function; maintenance of oxygenation, serial determination of arterial blood gases, pH, kidney function (serum creatinine), and electrolytes; and measurement of urinary output. Pulmonary edema may not appear for 24 hours.

Ensure optimal ventilation and oxygenation

The danger of hypoxemia exists even in the alert, conscious patient who appears to be breathing normally. Oxygen should be administered immediately at the highest available concentration. Oxygen saturation should be maintained at 90% or higher. Endotracheal intubation and mechanical ventilation are necessary for patients unable to maintain an open airway, adequate oxygenation, or ventilation. Nasogastric suctioning can decompress the stomach, aid in removal of swallowed water and reduce the risk of aspiration. Continuous positive airway pressure (CPAP) is an effective noninvasive way of reversing hypoxia and hypercarbia in patients with spontaneous respirations and a patent airway. Positive end-expiratory pressure (PEEP) is also effective for treating respiratory insufficiency. Serial physical examinations and chest radiographs should be carried out to detect possible pneumonitis, atelectasis, and pulmonary edema. Bronchodilators may be used to treat wheezing and bronchospasms due to aspiration. Antibiotics are reserved for clinical evidence of infection and should not be given prophylactically.

Cardiovascular support

Intravascular volume status must be monitored to determine whether vascular fluid replacement and pressors or diuretics are needed. This can be done by monitoring central venous pressure (or, preferably, pulmonary artery wedge pressure). If low cardiac output persists after adequate intravascular volume is achieved, pressors should be given. Standard therapy for hypotension and pulmonary edema is administered.

Correction of blood pH and electrolyte abnormalities

Metabolic acidosis is present in 70% of near-drowning victims, but it is usually corrected through adequate ventilation and oxygenation. Glycemic control improves outcome.

Cerebral injury

Central nervous system damage may progress despite apparently adequate treatment of hypoxia and shock. Mild hyperventilation to achieve a $PaCO_2$ of approximately 30 mm Hg is recommended to lower intracranial pressure. Standard treatment for brain and spinal cord injury must be followed.

Hypothermia

Core temperature should be measured and managed as appropriate (see Systemic Hypothermia, above).

Course & Prognosis

Victims of near drowning who have had prolonged hypoxemia should remain under close hospital observation for 2–3 days after all supportive measures have been withdrawn and clinical and laboratory findings have been stable. Long-term complications of near drowning may include neurologic impairment, seizure disorder, and pulmonary or cardiac damage.

Dysbarism & Decompression Sickness

Essentials of Diagnosis

- Symptoms temporally related to recent diving, altitude or pressure changes.
- Early recognition and prompt treatment of decompression sickness are extremely important.
- Consultation with diving medicine or hyperbaric oxygen specialist is indicated.

General Considerations

Dysbarism and decompression sickness (DCS) are physiologic problems that result from environmental pressure effects in gases in the body during underwater descent and ascent. These are hazards for fliers and for divers who are involved in recreational diving (eg, scuba diving), deep-water exploration, rescue or salvage operations, or construction. These may also occur in an air traveler when the aircraft cabin in not adequately pressurized during rapid ascent or descent between sea level and high altitudes.

Physics laws describe the mechanisms involved in dysbarism and DCS. As a diver descends, the gases in the body compress; gases dissolve in blood and tissues. These gases are in compressible (eg, lungs, gastrointestinal) and noncompressible (eg, sinuses, joints) areas of the body. At low depths the greatly increased pressure (eg, at 30 meters [100 feet] the pressure is four times greater than at the surface) compresses the respiratory gases into the blood and other tissues. During the ascent, gases in the body expand. This depends on the difference between the atmospheric pressure and the partial pressure of the gas dissolved in the tissues. If the ascent is too rapid, gas bubbles will form and cause damage depending on their location. DCS symptoms depends on the size and number and location of gas bubbles released (notably nitrogen). This may occur if airplane travel is taken too soon after diving. Conservative recommendation is to avoid high altitudes (air travel or ground ascent) for at least 24 hours after surfacing from the dive.

Risk of DCS depends on the dive details (depth, duration, number of dives, and interval surface time between dives, water conditions) as well as the diver's age, weight, physical condition, physical exertion, and the rate of ascent. Predisposing factors for DCS include obesity, injury, hypoxia, lung or cardiac disease, right to left cardiac shunt, diver's overall health, dehydration, alcohol and medication effects, and panic attacks. DCS also occurs in those who take hot showers after cold dives, or take air travel too soon. Asthma, pneumothorax, reduced pulmonary function, lung cysts, or thoracic trauma, cardiovascular disease, history of bowel obstruction, recent brain or eye surgery, seizures, diabetes and hypoglycemic episodes may be considered contraindications to diving.

Clinical Findings

The range of clinical manifestations varies depending on the location of the gas bubble formation or the compressibility of gases in the body. Symptom onset may be immediate, within minutes or hours (in the majority), or present up to 36 hours later. DCS symptoms include pain in the joints ("the bends"); skin pruritus or burning (skin bends); rashes; spinal cord or cerebral symptoms ("dissociation" symptoms that do not follow typical distribution patterns); labyrinthine DCS ("the staggers," central vertigo); pulmonary DCS ("the chokes," inspiratory pain, cough, and respiratory distress); arterial gas embolism (cerebral, pulmonary); barotrauma of the lungs, ear and sinus; dysbaric osteonecrosis; and coma. Reported sequelae include hemiparesis, neurologic dysfunction, and bone damage.

The onset of acute decompression symptoms occurs within 30 minutes in half of cases and almost invariably within 6 hours. Symptoms, which are highly variable, include pain (largely in the joints), headache, fatigue, numbness, confusion, pruritic rash, visual disturbances, nausea, vomiting, loss of hearing, weakness, paralysis, dizziness, vertigo, dyspnea, paresthesias, aphasia, and coma.

Treatment

Early recognition and prompt treatment are extremely important. DCS must be considered if symptoms are temporally related to recent diving or altitude or pressure changes. Immediate consultation with diving medicine or hyperbaric oxygen specialist is indicated even if mild symptoms resolved, since relapses with worse outcomes have occurred. Continuous administration of 100% oxygen is indicated and beneficial for all patients. Aspirin may be given for pain. Opioids should be used very cautiously, since these may obscure the response to recompression. Rapid transportation to a hyperbaric treatment facility for recompression is imperative for DCS. If air transportation is chosen, the aircraft must maintain pressurization near sea level to avoid worsening

DCS. Preliminary research suggests some benefit to heliox, nonsteroidal anti-inflammatory and statin medicines, but larger studies are needed. It has been recommended, however, that decompression symptoms be treated whenever they are seen—even up to 2 weeks postinjury—since it is still possible to reduce morbidity. The clinician should be familiar with the nearest hyperbaric facility. The Divers Alert Network (DAN) is an excellent worldwide resource for emergency advice 24 hours daily for the management of diving-related conditions (www.diversalertnetwork.org, DAN USA 1-919-684-8111, see website for other international phone numbers).

Altitude-Related Illness

Essentials of Diagnosis

- The severity of the altitude illness correlates with the rate and height of ascent, and the individual's susceptibility.
- Prompt recognition and medical attention of early symptoms of altitude illness should prevent progression.

General Considerations

High altitude medical problems are due to hypobaric hypoxia at high altitudes (greater than 2000 meters or 6560 feet). This usually results from increased physical activity with insufficient acclimatization, inadequate education and preparation, and individual susceptibility (preexisting medical conditions and medication use). Individual susceptibility is a key determinant of the risk of high altitude illness. Presentations may be acute, subacute, or chronic disturbances that result from hypobaric hypoxia. Acclimatization to altitudes above 5500 m (18,045 ft) is incomplete or physiologically impossible, although individual differences in tolerance to hypoxia exist.

The severity of the altitude-related illness correlates with the rapid rate and height of ascent and the individual's susceptibility. Susceptible underlying conditions include cardiac and pulmonary dysfunction, patent foramen ovale, blood disorders (ie, sickle cell disease), pregnancy, neurologic condition, recent surgery, and many others. Those with symptomatic cardiac or pulmonary disease should avoid high altitudes. High altitude illness comprises a spectrum of conditions based on end-organ effects. Manifestations of altitude illness are: (1) acute mountain sickness (AMS), (2) high-altitude pulmonary edema (HAPE), (3) high-altitude cerebral edema (HACE), (4) subacute mountain sickness, and (5) chronic mountain sickness (Monge disease).

Preventive measures include participant education, medical prescreening, pre-trip planning, and optimal physical conditioning before travel; adequate rest and sleep the day before travel; reduced food intake; and avoidance of alcohol, tobacco, and unnecessary physical activity during travel; slow ascent to allow acclimatization (300 meters or 984 feet per day); and a period of rest and inactivity for 1–2 days after arrival at high altitudes. Mountaineering parties at levels of 3000 meters (9840 feet) or higher should carry a supply of oxygen and medical equipment sufficient for several days.

Prophylactic medications may be prescribed if no contraindications exist. Acetazolamide, 250 mg orally every 8–12 hours, may be started on the day before ascent and continued for 48–72 hours at high altitude. Dexamethasone, 4 mg orally every 12 hours beginning on the day of ascent, continuing for 3 days at the higher altitude, and then tapering over 5 days, is an alternative. Research also suggests potential benefit from prophylaxis with sumatriptan, nifedipine, dexamethasone, tadalafil, and salmeterol (125 mcg by inhaler every 12 hours beginning 24 hours prior to ascent).

Acute Mountain Sickness (AMS)

Initial manifestations of AMS include headache (most severe and persistent symptom), lassitude, drowsiness, dizziness, chilliness, nausea and vomiting, facial pallor, dyspnea, and cyanosis. Later symptoms include facial flushing, irritability, difficulty concentrating, vertigo, tinnitus, visual and auditory disturbances, anorexia, insomnia, increased dyspnea and weakness on exertion, increased headaches (due to cerebral edema), palpitations, tachycardia, Cheyne-Stokes breathing, and weight loss. More severe manifestations include pulmonary and cerebral edema (HAPE and HACE; see below).

Initial treatment involves oxygen administration, voluntary periodic hyperventilation, which will often relieve acute symptoms. If immediate descent is not possible, portable hyperbaric chambers can provide symptomatic relief.

Acetazolamide (250 mg orally every 8–12 hours) remains the most effective medication for treatment of AMS and for more severe forms of altitude-related conditions. Dexamethasone (8 mg orally initially followed by 4 mg every 6 hours) is effective for treatment of AMS and acute cerebral edema. Both are recommended therapy for as long as symptoms persist and may be used together in severe cases. In most individuals, symptoms clear within 24–48 hours.

Definitive treatment is immediate descent. Descent is essential if the symptoms are persistent, severe, or worsening or if HAPE or HACE are present.

Acute High-Altitude Pulmonary Edema (HAPE)

HAPE is a serious complication and the leading cause of death from altitude illness. The hallmark is markedly elevated pulmonary artery pressure followed by pulmonary edema. It usually occurs at levels above 3000 meters (9840 feet). Early symptoms may appear within 6–36 hours after arrival at a high-altitude area. These include incessant dry cough, shortness of breath disproportionate to exertion, headache, decreased exercise performance, fatigue, dyspnea at rest, and chest tightness. Recognition of the early symptoms may enable the patient to descend before incapacitating pulmonary edema develops. Strenuous exertion should be avoided. An early descent of even 500 or 1000 meters may result in improvement of symptoms. Later, wheezing, orthopnea, and hemoptysis may occur as pulmonary edema worsens. Physical findings include tachycardia, mild fever, tachypnea, cyanosis, prolonged respiration, and rales and rhonchi. The clinical picture may resemble severe pneumonia. The patient may become confused or comatose. Diagnosis is usually clinical; ancillary tests are nonspecific or unavailable on site. The white count is often slightly elevated, but the erythrocyte sedimentation rate is usually normal. Chest radiographic findings vary from irregular patchy infiltration in one lung to nodular densities bilaterally or with transient prominence of the central pulmonary arteries. Transient nonspecific ECG changes, occasionally showing right ventricular strain, may occur. Pulmonary arterial blood pressure is elevated, whereas wedge pressure is normal. Research has shown benefits from chest ultrasonography for diagnosis and monitoring of HAPE.

Treatment must often be initiated under field conditions. Prompt recognition and medical attention of early symptoms prevent progression. The patient must rest in the semi-Fowler position (head raised), and 100% oxygen must be administered. *Immediate descent (at least 610 meters [2000 feet]) is essential.* Recompression in a portable hyperbaric bag will temporarily reduce symptoms if rapid or immediate descent is not possible. To conserve oxygen, lower flow rates (2–4 L/min) may be used until the victim recovers or is evacuated to a lower altitude and SaO_2 90%. Treatment for ARDS (see Chapter 9: Pulmonary Disorders) may be required for some patients. Calcium channel blockers and selective phosphodiesterase type 5 (PDE5) inhibitors are effective for symptomatic relief. Nifedipine, 10 mg initially followed by 30 mg slow-release tablets every 12 hours is recommended. Dexamethasone, 4 mg every 6 hours, has been recommended if central nervous system symptoms are present. Acetazolamide, 250 mg every 8–12 hours, should be administered if AMS is suspected.

Acute High-Altitude Cerebral Edema (HACE)

HACE appears to be an extension of the central nervous system symptoms of AMS and results from cerebral vasogenic edema and hypoxia. It usually occurs at elevations above 2500 meters (8250 feet) and is more common in unacclimatized individuals. Hallmarks are altered consciousness and ataxic gait; the patient appears "mildly drunk". Severe headaches, confusion, truncal ataxia, urinary retention or incontinence, focal deficits, papilledema, nausea, vomiting, and seizures may also occur and progress to obtundation and coma. High-altitude retinopathy is a separate but related effect of altitude. It can include dilated vessels, retinal hemorrhage, vitreous hemorrhage, and papilledema.

Treatment is immediate descent for at least 610 meters (2000 feet), continuing until symptoms improve. Oxygen (100% 2–4 L/min) should be administered by mask. Dexamethasone, 4–8 mg orally every 6 hours, is recommended thereafter. If immediate descent is impossible, a portable hyperbaric chamber should be used until symptomatic improvement occurs.

Subacute Mountain Sickness

This occurs most frequently in unacclimatized individuals and at altitudes above 4500 meters (14,764 feet). Symptoms of dyspnea and cough are probably due to hypoxic pulmonary hypertension and secondary congestive heart failure. Dehydration, skin dryness, and pruritus also can occur. The hematocrit may be elevated, and there may be ECG and chest radiographic evidence of right ventricular hypertrophy. Treatment consists of rest, oxygen administration, diuretics, and return to lower altitudes.

Chronic Mountain Sickness (Monge Disease)

This uncommon condition is seen in residents of high-altitude communities who have lost their acclimatization to such an environment. It is difficult to differentiate from chronic pulmonary disease. The disorder is characterized by somnolence, mental depression, cyanosis, clubbing of fingers, chronic hypoxia, hemoglobin > 22 g/dL, polycythemia (hematocrit often > 75%), signs of right ventricular failure, ECG evidence of right axis deviation and right atrial and ventricular hypertrophy, and radiographic evidence of right heart enlargement and central pulmonary vessel prominence, and pulmonary hypertension in some cases. There is no radiographic evidence of structural pulmonary disease. Pulmonary function tests usually disclose alveolar hypoventilation and elevated $PaCO_2$ but fail to reveal defective oxygen transport. There is a diminished respiratory response to CO_2.

Almost complete disappearance of all abnormalities eventually occurs when the patient returns to sea level. Recommended treatments include phlebotomy, oxygen supplementation, respiratory training, medroxyprogesterone (20–60 mg/d orally for 10 weeks), acetazolamide (250 mg/d orally for 3 weeks) and enalapril (5 mg orally daily).

When to Admit

- All patients with HAPE or HACE should be hospitalized for further observation.
- Hospitalization should also be considered for any patient who remains symptomatic after treatment and descent. Pulmonary symptoms and hypoxia may be

worsened by pulmonary embolism, bacterial pneumonia, or bronchitis.

Medical Safety of Air Travel & Selection of Patients for Air Travel

The medical safety of air travel depends not only on the nature and severity of the traveler's condition but also on other factors such as the duration and frequency of traveler's air travel, cabin pressurization, availability of medical supplies (including supplemental oxygen), presence of health care professionals on board, and traveler's preflight condition. Airline policies, charges, and other details regarding on-board medical capabilities must be checked with the airline carrier prior to flight. Air travel passengers are susceptible to a wide range of problems: pulmonary (eg, thromboembolism), cardiovascular, gastrointestinal, ocular, immunologic, syncope, neuropsychiatric, metabolic, and substance related. Occupational and frequent flyers are at risk for these as well as radiation, infection, circadian disturbance, and pressurization problems.

Hypobaric hypoxia is the underlying etiology of most serious medical emergencies in flight. Requirements for commercial aircraft are to maintain cabin pressurized to the equivalent of 8000 feet or less. Despite commercial aircraft pressurization requirements, there is significant hypoxemia, dyspnea, and stress in travelers with underlying serious cardiopulmonary and other conditions.

Research also demonstrates an association between venous thrombosis and air travel. The risk of severe pulmonary embolism occurring after air travel increases proportionally with the flight duration. Risk is up to 4.8 per million in flight durations of more than 12 hours. The absolute risk of a symptomatic venous thrombosis within 4 weeks of travel is 1/4600 flights longer than 4 hours. Travelers can take preventive measures by wearing support hose and engaging in in-flight leg exercises and walking. Air travel complications may be reduced by the following preventive measures: passenger education, passenger prescreening (especially those who have had recent surgery or an emergency condition, and those with chronic serious medical conditions). Travelers with pulmonary disease must have preflight medical assessment to determine whether supplemental oxygen is required. This is determined by an arterial oxygen tension of less than 70 mm Hg or pulse oximetry less than 92%. Other useful tests include the hypoxia altitude simulation test and the 6-minute walk test.

The Air Transport Association of America defines an incapacitated passenger as "one who is suffering from a physical or mental disability and who, because of such disability or the effect of the flight on the disability, is incapable of self-care; would endanger the health or safety of such person or other passengers or airline employees; or would cause discomfort or annoyance of other passengers." Air travel is not advised for anyone with an active pneumothorax, class III and IV pulmonary hypertension, acute worsening of an underlying lung disease, or any unstable conditions. Unstable conditions include poorly controlled hypertension, dysrhythmias, angina, valvular disease, congestive heart failure, or psychiatric condition; severe anemia or sickle cell disease; recent myocardial infarction, cerebrovascular accident, or deep venous thrombosis; postsurgery, especially heart surgery (unless approved by surgeon); and any active communicable disease (tuberculosis, measles, chickenpox, or other communicable virulent infections). Airlines must provide in-flight medical equipment maintenance, flight crew medical training, and steady cabin pressurization. Passengers with motion sickness or ear pressurization problems should take medications prior to and during the flight to reduce symptoms. Small meals of easily digested food and avoidance of carbonated beverages before and during the flight may reduce the tendency to nausea and vomiting.

Pregnancy and Infancy

Pregnant women may be permitted to fly during the first 8 months of pregnancy unless there is a history of pregnancy complications or premature birth. A physician's authorization is required if travel is essential during the ninth month of pregnancy. Infants less than 1 week old should not be flown at high altitudes or for long distances.

Initial Evaluation: Poisoning or Overdose

Patients with drug overdoses or poisoning may initially have no symptoms or they may have varying degrees of overt intoxication. The asymptomatic patient may have been exposed to or may have ingested a lethal dose of a poison but not yet exhibit any manifestations of toxicity. It is important to (1) quickly assess the potential danger, (2) consider gut decontamination to prevent absorption, and (3) observe the patient for an appropriate interval.

Assess the Danger

If the drug or poison is known, its danger can be assessed by consulting a text or computerized information resource (eg, Poisindex) or by calling a regional poison control center. (In the United States, dialing 800-222-1222 will direct the call to the regional poison control center.) Assessment will usually take into account the dose ingested; the time interval since ingestion; the presence of any symptoms or clinical signs; preexisting cardiac, respiratory, kidney, or liver disease; and, occasionally, specific serum drug or toxin levels. Be aware that the history given by the patient or family may be incomplete or unreliable.

The manufacturer or its local representative may be able to provide information over the phone concerning the toxic ingredients in question and can be contacted directly or via the regional poison control center.

Gut Decontamination

The choice of gut decontamination procedure depends on the toxin and the circumstances. (See below for a more detailed discussion of methods.)

Immediate 24-Hour Toxicology Consultation
Call your regional poison control center
U.S. toll-free 1-800-222-1222

Observation of the Patient

Asymptomatic or mildly symptomatic patients should be observed for at least 4–6 hours. Longer observation is indicated if the ingested substance is a sustained-release preparation or is known to slow gastrointestinal motility or if there may have been exposure to a poison with delayed onset of symptoms (such as acetaminophen, colchicine, or hepatotoxic mushrooms). After that time, the patient may be discharged if no symptoms have developed and adequate gastric decontamination has been provided. Before discharge, psychiatric evaluation should be performed to assess suicidal risk. Intentional ingestions in adolescents should raise the possibility of unwanted pregnancy or sexual abuse.

The Symptomatic Patient

In symptomatic patients, treatment of life-threatening complications takes precedence over in-depth diagnostic evaluation. Patients with mild symptoms may deteriorate rapidly, which is why all potentially significant exposures should be observed in an acute care facility. The following complications may occur, depending on the type of poisoning.

Coma

Assessment & Complications

Coma is commonly associated with ingestion of large doses of antihistamines, benzodiazepines and other sedative-hypnotic drugs, -hydroxybutyrate (GHB), ethanol, opioids, antipsychotic drugs, or antidepressants. The most common cause of death in comatose patients is respiratory failure, which may occur abruptly. Pulmonary aspiration of gastric contents may also occur, especially in victims who are deeply obtunded or convulsing. Hypoxia and hypoventilation may cause or aggravate hypotension, arrhythmias, and seizures. Thus, protection of the airway and assisted ventilation are the most important treatment measures for any poisoned patient.

Treatment

Emergency Management

The initial emergency management of coma can be remembered by the mnemonic *ABCD*, for *A*irway, *B*reathing, *C*irculation, and *D*rugs (dextrose, thiamine, and naloxone or flumazenil), respectively.

Airway

Establish a patent airway by positioning, suction, or insertion of an artificial nasal or oropharyngeal airway. If the patient is deeply comatose or if there is no gag or cough reflex, perform endotracheal intubation. These airway interventions may not be necessary if the patient is intoxicated by an opioid or a benzodiazepine and responds rapidly to intravenous naloxone or flumazenil (see below).

Breathing

Clinically assess the quality and depth of respiration, and provide assistance if necessary with a bag-valve-mask device or mechanical ventilator. Provide supplemental oxygen. The arterial blood CO_2 tension is useful in determining the adequacy of ventilation. The arterial blood PO_2 determination may reveal hypoxemia, which may be caused by respiratory arrest, bronchospasm, pulmonary aspiration, or noncardiogenic pulmonary edema. Pulse oximetry provides an assessment of oxygenation but is not reliable in patients with methemoglobinemia or carbon monoxide poisoning, unless a newer oximetry device capable of detecting these forms of hemoglobin is used (eg, the Masimo Rad-57 pulse CO-oximeter).

Circulation

Measure the pulse and blood pressure and estimate tissue perfusion (eg, by measurement of urinary output, skin signs, arterial blood pH). Place the patient on continuous ECG monitoring. Insert an intravenous line, and draw blood for glucose, electrolytes, serum creatinine and liver tests, and possible quantitative toxicologic testing.

Drugs

Dextrose and thiamine

Unless promptly treated, severe hypoglycemia can cause irreversible brain damage. Therefore, in all comatose or convulsing patients, give 50%dextrose, 50–100 mL by intravenous bolus, unless a rapid bedside blood sugar test is available and rules out hypoglycemia. In alcoholic or very malnourished patients who may have marginal thiamine stores, give thiamine, 100 mg intramuscularly or over 2–3 minutes intravenously.

Narcotic antagonists

Naloxone, 0.4–2 mg intravenously, may reverse opioid-induced respiratory depression and coma. It is often given empirically to any comatose patient with depressed respirations. If opioid overdose is strongly suspected, give additional doses of naloxone (up to 5–10 mg may be required to reverse the effects of potent opioids or propoxyphene). **Note:** Naloxone has a much shorter duration of action (2–3 hours) than most common opioids; repeated doses may be required, and continuous observation for at least 3–4 hours after the last dose is mandatory. Nalmefene, a newer opioid antagonist, has a duration of effect longer than that of naloxone but still shorter than that of the opioid methadone.

Flumazenil

Flumazenil, 0.2–0.5 mg intravenously, repeated every 30 seconds as needed up to a maximum of 3 mg, may reverse benzodiazepine-induced coma. **Caution:** Flumazenil should **not** be given if the patient has coingested a tricyclic antidepressant, is a user of high-dose benzodiazepines, or has a seizure disorder because its use in these circumstances may precipitate seizures. *In most circumstances, use of flumazenil is not advised as the potential risks outweigh its benefits.* **Note:** Flumazenil has a short duration of effect (2–3 hours), and resedation requiring additional doses is common.

Hypothermia

Assessment & Complications

Hypothermia commonly accompanies coma due to opioids, ethanol, hypoglycemic agents, phenothiazines, barbiturates, benzodiazepines, and other sedative-hypnotics and central nervous system depressants. Hypothermic patients may have a barely perceptible pulse and blood pressure. Hypothermia may cause or aggravate hypotension, which will not reverse until the temperature is normalized.

Treatment

Treatment of hypothermia is discussed in Chapter 37: Disorders Due to Physical Agents. Gradual rewarming is preferred unless the patient is in cardiac arrest.

Hypotension

Assessment & Complications

Hypotension may be due to poisoning by many different drugs and poisons, including antihypertensive drugs, -blockers, calcium channel blockers, disulfiram (ethanol interaction), iron, trazodone, quetiapine, and other antipsychotic agents and antidepressants. Poisons causing hypotension include cyanide, carbon monoxide, hydrogen sulfide, arsenic, and certain mushrooms.

Hypotension in the poisoned or drug-overdosed patient may be caused by venous or arteriolar vasodilation, hypovolemia, depressed cardiac contractility, or a combination of these effects. The only certain way to determine the cause of hypotension in any individual patient is to insert a pulmonary artery catheter and calculate the cardiac output and peripheral vascular resistance. Alternatively, a central venous pressure (CVP) monitor may indicate a need for further fluid therapy.

Treatment

Most patients respond to empiric treatment with repeated 200 mL intravenous boluses of 0.9% saline or other isotonic crystalloid up to a total of 1–2 L; much larger amounts may be needed if the victim is profoundly volume depleted. If fluid therapy is not successful, give dopamine, 5–15 mcg/kg/min by intravenous infusion. Consider pulmonary artery catheterization if hypotension persists.

Hypotension caused by certain toxins may respond to specific treatment. For hypotension caused by overdoses of tricyclic antidepressants or related drugs, administer sodium bicarbonate, 50–100 mEq by intravenous bolus injection. Norepinephrine 4–8 mcg/min by intravenous infusion is more effective than dopamine in some patients with overdoses of tricyclic antidepressants or of drugs with predominantly vasodilating effects. For -blocker overdose, glucagon (5–10 mg intravenously) may be of value. For calcium channel blocker overdose, administer calcium chloride, 1–2 g intravenously (repeated doses may be necessary; doses of 5–10 g and more have been given in some cases). High-dose insulin euglycemic therapy may also be used (see Calcium Channel Blockers, below). Intralipid 20% lipid emulsion has been reported to improve hemodynamics in human case reports or animal studies of intoxication by highly lipid-soluble drugs such as bupivacaine, bupropion, clomipramine, and verapamil.

Sirianni AJ et al. Use of lipid emulsion in the resuscitation of a patient with prolonged cardiovascular collapse after overdose of bupropion and lamotrigine. Ann Emerg Med. 2008 Apr;51(4):412–5. [PMID: 17766009]

Hypertension

Assessment & Complications

Hypertension may be due to poisoning with amphetamines, anticholinergics, cocaine, yohimbine-containing performance-enhancing products, monoamine oxidase (MAO) inhibitors, and other drugs.

Severe hypertension (eg, diastolic blood pressure > 105–110 mm Hg in a person who does not have chronic hypertension) can result in acute intracranial hemorrhage, myocardial infarction, or aortic dissection.

Treatment

Treat hypertension if the patient is symptomatic or if the diastolic pressure is greater than 105–110 mm Hg—especially if there is no prior history of hypertension.

Hypertensive patients who are agitated or anxious may benefit from a sedative such as lorazepam, 2–3 mg intravenously. For persistent hypertension, administer phentolamine, 2–5 mg intravenously, or nitroprusside sodium, 0.25–8 mcg/kg/min intravenously. If excessive tachycardia is present, add propranolol, 1–5 mg intravenously, or esmolol, 25–100 mcg/kg/min intravenously, or labetalol 0.2–0.3 mg/kg intravenously.
Caution: Do not give -blockers alone, since doing so may paradoxically worsen hypertension as a result of unopposed -adrenergic stimulation.

Wang NE et al. Hypertensive crisis and NSTEMI after accidental overdose of sustained release pseudoephedrine: a case report. Clin Toxicol (Phila). 2008 Nov;46(9):922–3. [PMID: 18608273]

Arrhythmias

Assessment & Complications

Arrhythmias may occur with a variety of drugs or toxins (Table 38–1). They may also occur as a result of hypoxia, metabolic acidosis, or electrolyte imbalance (eg, hyperkalemia, hypokalemia, hypomagnesemia or hypocalcemia), or following exposure to chlorinated solvents or chloral hydrate overdose. Atypical ventricular tachycardia (torsades de pointes) is often associated with drugs that prolong the QT interval.

Table 38–1. Common toxins or drugs causing arrhythmias.

Arrhythmia	**Common Causes**
Sinus bradycardia	-Blockers, calcium channel blockers, clonidine, digitalis glycosides, organophosphates
Atrioventricular block	-Blockers, calcium channel blockers, class Ia antiarrhythmics (including quinidine), carbamazepine, clonidine, digitalis glycosides, lithium
Sinus tachycardia	-Agonists (eg, albuterol), amphetamines, anticholinergics, antihistamines, caffeine, cocaine, pseudoephedrine, tricyclic and other antidepressants

Wide QRS complex	Class Ia and class Ic antiarrhythmics, phenothiazines (eg, thioridazine), potassium (hyperkalemia), propranolol, tricyclic antidepressants, diphenhydramine (severe overdose)
QT interval prolongation and torsades de pointes	Arsenic, class Ia and class III antiarrhythmics, droperidol, lithium, methadone, pentamidine, sotalol, thioridazine, venlafaxine, and many other drugs (see http://www.azcert.org/medical-pros/drug-lists/drug-lists.cfm)
Ventricular premature beats and ventricular tachycardia	Amphetamines, cocaine, ephedrine, caffeine, chlorinated or fluorinated hydrocarbons, digoxin, aconite (found in some Chinese herbal preparations), fluoride; theophylline. QT prolongation can lead to atypical ventricular tachycardia (torsades de pointes)

[1] Arrhythmias may also occur as a result of hypoxia, metabolic acidosis, or electrolyte imbalance (eg, hyperkalemia or hypokalemia, hypocalcemia).

Treatment

Arrhythmias are often caused by hypoxia or electrolyte imbalance, and these conditions should be sought and treated. If ventricular arrhythmias persist, administer lidocaine or amiodarone at usual antiarrhythmic doses. **Note:** Wide QRS complex tachycardia in the setting of tricyclic antidepressant overdose (or quinidine and other class Ia drugs) should be treated with sodium bicarbonate, 50–100 mEq intravenously by bolus injection. (See discussion of tricyclic antidepressant poisoning.) **Caution:** Avoid class Ia agents (quinidine, procainamide, disopyramide), which may aggravate arrhythmias caused by tricyclic antidepressants. Torsades de pointes associated with prolonged QT interval may respond to intravenous magnesium (2 g intravenously over 2 minutes) or overdrive pacing. Treat digitalis-induced arrhythmias with digoxin-specific antibodies (see discussion of cardiac glycoside poisoning).

For tachyarrhythmias induced by chlorinated solvents, chloral hydrate, Freons, or sympathomimetic agents, use propranolol or esmolol (see doses given above in Hypertension section).

Tarabar AF et al. Citalopram overdose: late presentation of torsades de pointes (TdP) with cardiac arrest. J Med Toxicol. 2008 Jun;4(2):101–5. [PMID: 18570170]

Seizures

Assessment & Complications

Seizures may be due to poisoning with many poisons and drugs, including amphetamines, antidepressants (especially tricyclic antidepressants, bupropion, and venlafaxine), antihistamines (especially diphenhydramine), antipsychotics, cocaine, isoniazid (INH), and theophylline.

Seizures may also be caused by hypoxia, hypoglycemia, hypocalcemia, hyponatremia, withdrawal from alcohol or sedative-hypnotics, head trauma, central nervous system infection, or idiopathic epilepsy.

Prolonged or repeated seizures may lead to hypoxia, metabolic acidosis, hyperthermia, and rhabdomyolysis.

Treatment

Administer lorazepam, 2–3 mg, or diazepam, 5–10 mg, intravenously over 1–2 minutes, or—if intravenous access is not immediately available—midazolam, 5–10 mg intramuscularly. If convulsions continue, administer phenobarbital, 15–20 mg/kg slowly intravenously over no less than 30 minutes; or phenytoin, 15 mg/kg intravenously over no less than 30 minutes (maximum infusion rate, 50 mg/min). For drug-induced seizures, phenobarbital is generally preferred over phenytoin. Propofol infusion has also been reported effective for some resistant drug-induced seizures.

Seizures due to a few drugs and toxins may require antidotes or other specific therapies (as listed in Table 38–2).

Table 38–2. Seizures related to toxins or drugs requiring special consideration.[1]

Toxin or Drug	**Comments**
Methylenedioxymethamphetamine (MDMA; "Ecstasy")	Seizures may be due to hyponatremia.
Isoniazid	Administer pyridoxine.
Lithium	May indicate need for hemodialysis.
Organophosphates	Administer pralidoxime (2-PAM) and atropine.
Strychnine	"Seizures" are actually spinally mediated muscle spasms and usually require neuromuscular paralysis.
Theophylline	Seizures indicate need for

	hemodialysis.
Tricyclic antidepressants	Hyperthermia and cardiotoxicity are common complications of repeated seizures; paralyze early with neuromuscular blockers to reduce muscular hyperactivity.

[1] See text for dosages.

Thundiyil JG et al. Evolving epidemiology of drug-induced seizures reported to a Poison Control Center System. J Med Toxicol. 2007 Mar;3(1):15–9. [PMID: 18072153]

Hyperthermia

Assessment & Complications

Hyperthermia may be associated with poisoning by amphetamines (especially methylenedioxymethamphetamine [MDMA; "Ecstasy"]), atropine and other anticholinergic drugs, cocaine, salicylates, strychnine, tricyclic antidepressants, and various other medications. Overdoses of serotonin reuptake inhibitors (eg, fluoxetine, paroxetine, sertraline) or their use in a patient taking an MAO inhibitor may cause agitation, hyperactivity, myoclonus, and hyperthermia ("serotonin syndrome"). Antipsychotic agents can cause rigidity and hyperthermia (neuroleptic malignant syndrome [NMS]). (See section on Schizophrenic & Other Psychotic Disorders in Chapter 25: Psychiatric Disorders.) Malignant hyperthermia is a rare disorder associated with general anesthetic agents.

Hyperthermia is a rapidly life-threatening complication. Severe hyperthermia (temperature > 40–41 °C) may rapidly cause brain damage and multiorgan failure, including rhabdomyolysis, advanced chronic kidney disease, and coagulopathy (see Chapter 37: Disorders Due to Physical Agents).

Treatment

Treat hyperthermia aggressively by removing all clothing, spraying the patient with tepid water, and fanning the patient. If this is not rapidly effective, as shown by a normal rectal temperature within 30–60 minutes, or if there is significant muscle rigidity or hyperactivity, induce neuromuscular paralysis with a nondepolarizing neuromuscular blocker (eg, rocuronium, vecuronium). Once paralyzed, the patient must be intubated and mechanically ventilated. In patients with seizures, absence of visible muscular convulsive movements may give the false impression that brain seizure activity has ceased; however, this must be confirmed by electroencephalography.

Dantrolene (2–5 mg/kg intravenously) may be effective for hyperthermia associated with muscle rigidity that does not respond to neuromuscular blockade (ie, malignant hyperthermia). Bromocriptine, 2.5–7.5 mg orally daily, has been recommended for neuroleptic malignant syndrome. Cyproheptadine, 4 mg orally every hour for three or four doses, has been used to treat serotonin syndrome.

Dvir Y et al. Serotonin syndrome: a complex but easily avoidable condition. Gen Hosp Psychiatry. 2008 May–Jun;30(3):284–7. [PMID: 18433663]

Antidotes & Other Treatment

Antidotes

Give an antidote (if available) when there is reasonable certainty of a specific diagnosis (Table 38–3). Antidotes themselves may have serious side effects. The indications and dosages for specific antidotes are discussed in the respective sections for specific toxins.

Table 38–3. Some toxic agents for which there are

specific antidotes.[1]

Toxic Agent	Specific Antidote
Acetaminophen	*N*-Acetylcysteine
Anticholinergics (eg, atropine)	Physostigmine
Anticholinesterases (eg, organophosphate pesticides)	Atropine and pralidoxime (2-PAM)
Benzodiazepines	Flumazenil (rarely used; see warning in text)
Carbon monoxide	Oxygen, hyperbaric oxygen
Cyanide	Sodium nitrite, sodium thiosulfate; hydroxocobalamin
Digitalis glycosides	Digoxin-specific Fab antibodies
Heavy metals (eg, lead, mercury, iron) and arsenic	Specific chelating agents
Isoniazid	Pyridoxine (vitamin B6)
Methanol, ethylene glycol	Ethanol (ethyl alcohol) or fomepizole (4-methylpyrazole)
Opioids	Naloxone, nalmefene

Snake venom	Specific antivenin

[1] See text for indications and dosages.

Decontamination of the Skin

Corrosive agents rapidly injure the skin and eyes and must be removed immediately. In addition, many toxins are readily absorbed through the skin, and systemic absorption can be prevented only by rapid action.

Wash the affected areas with copious quantities of lukewarm water or saline. Wash carefully behind the ears, under the nails, and in skin folds. For oily substances (eg, pesticides), wash the skin at least twice with plain soap and shampoo the hair. Specific decontaminating solutions or solvents (eg, alcohol) are rarely indicated and in some cases may paradoxically enhance absorption. For exposure to chemical warfare poisons such as nerve agents or vesicants, some authorities recommend use of a dilute hypochlorite solution (household bleach diluted 1:10 with water).

Decontamination of the Eyes

Act quickly to prevent serious damage. Flush the eyes with copious amounts of saline (preferred) or water. (If available, instill local anesthetic drops in the eye before beginning irrigation.) Remove contact lenses if present.

Direct the irrigating stream so that it will flow across the eyes after running off the nasal bridge. Lift the tarsal conjunctiva to look for undissolved particles and to facilitate irrigation. Continue irrigation for 15 minutes or until each eye has been irrigated with at least 1 L of solution. If the toxin is an acid or a base, check the pH of the tears after irrigation, and continue irrigation until the pH is between 6.5 and 7.5.

After irrigation is complete, perform a careful examination of the eye, using fluorescein and a slit lamp or Wood lamp to identify areas of corneal injury. Patients with serious conjunctival or corneal injury should be immediately referred to an ophthalmologist.

Gastrointestinal Decontamination

Removal of ingested poisons was a routine part of emergency treatment for decades. However, prospective clinical studies have failed to demonstrate improved outcome after gastric emptying. For small or moderate ingestions of most substances, toxicologists generally recommend oral activated charcoal alone without prior gastric emptying. Exceptions are large ingestions of anticholinergic compounds and salicylates, which often delay gastric emptying, and ingestion of sustained-release or enteric-coated tablets, which may remain intact for several hours.

Gastric emptying is not generally used for ingestion of corrosive agents or petroleum distillates, because further esophageal injury or pulmonary aspiration may result. However, in certain cases, removal of the toxin may be more important than concern over possible complications. Consult a medical toxicologist or regional poison control center (800-222-1222) for advice.

Emesis

Emesis using syrup of ipecac can partially evacuate gastric contents if given very soon after ingestion (eg, at work or at home). However, it may increase the risk of pulmonary aspiration and delay or prevent the use of oral activated charcoal. Therefore, it is no longer used in the routine management of ingestions.

Gastric Lavage

Gastric lavage is more effective for liquid poisons or small pill fragments than for intact tablets or pieces of mushroom. It is most useful when started within 60 minutes after ingestion. However, the lavage procedure may delay administration of activated charcoal and may stimulate vomiting and pulmonary aspiration in an obtunded patient.

Indications

Gastric lavage is sometimes used after very large ingestions (eg, massive aspirin overdose), for collection and examination of gastric contents for identification of poison; and for convenient administration of charcoal and antidotes.

Contraindications

Do *not* use lavage for stuporous or comatose patients with absent gag reflexes unless they are endotracheally intubated beforehand. Some authorities advise against lavage when caustic material has been ingested; others regard it as essential to remove liquid corrosives from the stomach.

Technique

In obtunded or comatose patients, the danger of aspiration pneumonia is reduced by performing endotracheal intubation with a cuffed tube before the procedure. Gently insert a lubricated, soft but noncollapsible stomach tube (at least 37–40 °F) through the mouth or nose into the stomach. Aspirate and save the contents, and then lavage repeatedly with 50- to 100-mL aliquots of fluid until the return fluid is clear. Use lukewarm tap water or saline.

Activated Charcoal

Activated charcoal effectively adsorbs almost all drugs and poisons. Poorly adsorbed substances include iron, lithium, potassium, sodium, mineral acids, and alcohols.

Indications

Activated charcoal should be used for prompt adsorption of drugs or toxins in the stomach and intestine. Studies in volunteers show that activated charcoal given alone may be as effective as or more effective than ipecac-induced emesis or gastric lavage. However, evidence of benefit in clinical studies is lacking. Administration of charcoal, especially if mixed with sorbitol, can provoke vomiting, which could lead to pulmonary aspiration in an obtunded patient.

Contraindications

Activated charcoal should not be used for comatose or convulsing patients unless it can be given by gastric tube and the airway is first protected by a cuffed endotracheal tube. It is also contraindicated for patients with ileus or intestinal obstruction or those who have ingested corrosives for whom endoscopy is planned.

Technique

Administer activated charcoal, 60–100 g orally or via gastric tube, mixed in aqueous slurry. Repeated doses may be given to ensure gastrointestinal adsorption or to enhance elimination of some drugs (see below).

Catharsis

Indications

Cathartics are used by some toxicologists for stimulation of peristalsis to hasten the elimination of unabsorbed drugs and poisons and the activated charcoal slurry. There is no clinical evidence to support their use, and some agents (eg, sorbitol) can provoke vomiting, increasing the risk of pulmonary aspiration.

Contraindications and Cautions

Do not give a cathartic to patients with suspected intestinal obstruction. Avoid sodium-based cathartics in patients with hypertension, advanced chronic kidney disease, and congestive heart failure and magnesium-based cathartics in patients with advanced chronic kidney disease. Sorbitol (an osmotic cathartic found in some prepackaged activated charcoal slurry products) can cause hypotension and dehydration due to third-spacing and also causes intestinal cramping and vomiting.

Whole Bowel Irrigation

Whole bowel irrigation uses large volumes of balanced polyethylene glycol-electrolyte solution to mechanically cleanse the entire intestinal tract. Because of the composition of the irrigating solution, there is no significant gain or loss of systemic fluids or electrolytes.

Indications

Whole bowel irrigation is particularly effective for massive iron ingestion in which intact tablets are visible on abdominal radiographs. It has also been used for ingestions of lithium, sustained-release and enteric-coated tablets, and swallowed drug-filled packets.

Contraindications

Do not use in patients with suspected intestinal obstruction. Use with caution in patients who are obtunded or have depressed airway protective reflexes.

Technique

Administer a balanced polyethylene glycol-electrolyte solution (CoLyte, GoLYTELY) into the stomach via gastric tube at a rate of 1–2 L/h until the rectal effluent is clear. This may take several hours. It is most effective when patients are able to sit on a commode to pass the intestinal contents.

Increased Drug Removal

Urinary Manipulation

Forced diuresis is hazardous; the risk of complications (pulmonary edema, electrolyte imbalance) usually outweighs its benefits. Acidic drugs (eg, salicylates, phenobarbital) are more rapidly excreted with an alkaline urine. Acidification (sometimes promoted for amphetamines, phencyclidine) is *not* very effective and is contraindicated in the presence of rhabdomyolysis or myoglobinuria.

Hemodialysis

The indications for dialysis are as follows: (1) Known or suspected potentially lethal amounts of a dialyzable drug (Table 38–4). (2) Poisoning with deep coma, apnea, severe hypotension, fluid and electrolyte or acid-base disturbance, or extreme body temperature changes that cannot be corrected by conventional measures. (3) Poisoning in patients with severe kidney, cardiac, pulmonary, or hepatic disease who will not be able to eliminate toxin by the usual mechanisms.

Table 38–4. Recommended use of hemodialysis in poisoning.[1]

Poison	**Indications**[1]
Carbamazepine	Seizures, severe cardiotoxicity; serum level > 60 mg/L
Ethylene glycol	Acidosis, serum level > 50 mg/dL
Lithium	Severe symptoms; level > 4 mEq/L more than 12 hours after last dose

Methanol	Acidosis, serum level > 50 mg/dL
Phenobarbital	Intractable hypotension, acidosis despite maximal supportive care
Salicylate	Severe acidosis, CNS symptoms, level > 100 mg/dL (acute overdose) or > 60 mg/dL (chronic intoxication)
Theophylline	Serum level > 90–100 mg/L (acute) or seizures and serum level > 40–60 mg/L (chronic)
Valproic acid	Serum level > 900–1000 mg/L or deep coma, severe acidosis

[1] See text for further discussion of indications.

CNS, central nervous system.

Continuous renal replacement therapy (also known as continuous venovenous hemodiafiltration) is of uncertain benefit for elimination of most poisons but has been used successfully in the management of lithium intoxication.

Repeat-Dose Charcoal

Repeated doses of activated charcoal, 20–30 g orally or via gastric tube every 3–4 hours, may hasten elimination of some drugs (eg, phenytoin, carbamazepine, dapsone) by absorbing drugs excreted into the gut lumen ("gut dialysis"). However, clinical studies have failed to prove better outcome using multiple-dose charcoal. Sorbitol or other cathartics should *not* be used with each dose, or resulting large stool volumes may lead to dehydration or hypernatremia.

Diagnosis of Poisoning

The identity of the ingested substance or substances is usually known, but occasionally a comatose patient is found with an unlabeled container or the patient is unable or unwilling to give a coherent history. By performing a directed physical examination and ordering common clinical laboratory tests, the clinician can often make a tentative diagnosis that may allow empiric interventions or may suggest specific toxicologic tests.

Physical Examination

Important diagnostic variables in the physical examination include blood pressure, pulse rate, temperature, pupil size, sweating, and the presence or absence of peristaltic activity. Poisonings with many drugs fit into one of four common syndromes.

Sympathomimetic Syndrome

The blood pressure and pulse rate are elevated, though with severe hypertension reflex bradycardia may occur. The temperature is often elevated, pupils are dilated, and the skin is sweaty, though mucous membranes are dry. Patients are usually agitated, anxious, or frankly psychotic.

Examples: Amphetamines, cocaine, ephedrine and pseudoephedrine.

Sympatholytic Syndrome

The blood pressure and pulse rate are decreased and body temperature is low. The pupils are small or even pinpoint. Peristalsis is usually decreased. Patients are usually obtunded or comatose.

Examples: Barbiturates, benzodiazepines and other sedative hypnotics, GHB, clonidine and related antihypertensives, ethanol, opioids.

Cholinergic Syndrome

Stimulation of muscarinic receptors causes bradycardia, miosis, sweating, and hyperperistalsis as well as bronchorrhea, wheezing, excessive salivation, and urinary incontinence. Nicotinic receptor stimulation may produce initial hypertension and tachycardia as well as fasciculations and muscle weakness. Patients are usually agitated and anxious.

Examples: Carbamates, nicotine, organophosphates (including nerve agents), physostigmine.

Anticholinergic Syndrome

Tachycardia with mild hypertension is common, and the body temperature is often elevated. Pupils are widely dilated. The skin is flushed, hot, and dry. Peristalsis is decreased, and urinary retention is common. Patients may have myoclonic jerking or choreoathetoid movements. Agitated delirium is frequently seen, and severe hyperthermia may occur.

Examples: Atropine, scopolamine, other naturally occurring and pharmaceutical anticholinergics, antihistamines, tricyclic antidepressants.

Laboratory Tests

The following clinical laboratory tests are recommended for screening of the overdosed patient: measured serum osmolality and osmol gap, electrolytes, glucose, creatinine, blood urea nitrogen (BUN), urinalysis (eg, oxalate crystals with ethylene glycol poisoning, myoglobinuria with rhabdomyolysis), and electrocardiography. Serum acetaminophen and ethanol quantitative levels should be determined in all patients with drug overdoses.

Osmol Gap

The osmol gap is defined and calculation of the gap is described in Table 38–5. It is increased in the presence of large quantities of low-molecular-weight substances, most commonly ethanol. Common poisons associated with increased osmol gap are acetone, ethanol, ethylene glycol, isopropyl alcohol, methanol, and propylene glycol. **Note:** Severe alcoholic ketoacidosis and diabetic ketoacidosis can also cause an elevated osmol gap resulting from the production of ketones and other low-molecular-weight substances.

Table 38–5. Use of the osmol gap in toxicology.
The osmol gap (osm) is determined by subtracting the calculated serum osmolality from the measured serum osmolality.

Serum osmolality may be increased by contributions of circulating alcohols and other low-molecular-weight substances. Since these substances are not included in the calculated osmolality, there will be a gap proportionate to their serum concentration and inversely proportionate to their molecular weight:

	Molecular Weight	**Toxic Concentration**	**Approximate Corresponding osm (mosm/L)**
Ethanol	46	300	65
Methanol	32	50	16
Ethylene glycol	60	100	16
Isopropanol	60	150	25

Note: The normal osmol gap may vary by as much as ± 10 mosm/L; thus, small osmol gaps may be unreliable in the diagnosis of poisoning.

Adapted, with permission, from Stone CK, Humphries RL (editors): *Current Emergency Diagnosis & Treatment*, 5th ed. McGraw-Hill, 2004.

Anion Gap

Metabolic acidosis associated with an elevated anion gap is usually due to an accumulation of lactic acid or other acids (see Chapter 21: Fluid & Electrolyte Disorders). Common causes of elevated anion gap in poisoning include carbon monoxide, cyanide, ethylene glycol, medicinal iron, INH, methanol, metformin, ibuprofen and salicylates.

The osmol gap should also be checked; combined elevated anion and osmol gaps suggests poisoning by methanol or ethylene glycol, though this may also occur in patients with diabetic ketoacidosis and alcoholic ketoacidosis.

Toxicology Laboratory Examination

A comprehensive toxicology screen is of little value in the initial care of the poisoned patient—on the contrary, it is time-consuming and expensive. Specific quantitative levels of certain drugs may be extremely helpful (Table 38–6), however, especially if specific antidotes or interventions (eg, dialysis) would be indicated based on the results.

Table 38–6. Specific quantitative levels and potential therapeutic interventions.[1]

Drug or Toxin	**Treatment**
Acetaminophen	Specific antidote (*N*-acetylcysteine) based on serum level
Carbon monoxide	High carboxyhemoglobin level indicates need for 100% oxygen, consideration of hyperbaric oxygen
Carbamazepine	High level may indicate need for hemodialysis
Digoxin	On basis of serum digoxin level and severity of clinical presentation, treatment with Fab antibody fragments (Digibind) may be indicated
Ethanol	Low serum level may suggest nonalcoholic cause of coma (eg, trauma, other drugs, other alcohols). Serum ethanol may also be useful in monitoring ethanol therapy for methanol or ethylene glycol poisoning.
Iron	Level may indicate need for chelation with deferoxamine
Lithium	Serum levels can guide decision to institute hemodialysis
Methanol, ethylene glycol	Acidosis, high levels indicate need for hemodialysis, therapy with ethanol or

	fomepizole
Methemoglobin	Methemoglobinemia can be treated with methylene blue intravenously
Salicylates	High level may indicate need for hemodialysis, alkaline diuresis
Theophylline	Immediate hemodialysis or hemoperfusion may be indicated based on serum level
Valproic acid	Elevated levels may indicate need to consider hemodialysis or L-carnitine therapy, or both

[1] Some drugs or toxins may have profound and irreversible toxicity unless rapid and specific management is provided outside of routine supportive care. For these agents, laboratory testing may provide the serum level or other evidence required for administering a specific antidote or arranging for hemodialysis.

If a toxicology screen is required, urine is the best specimen. Many hospitals can perform a quick but limited screen for "drugs of abuse" (typically these screens include only opiates, amphetamines, and cocaine, and some add benzodiazepines, barbiturates, and tetrahydrocannabinol [marijuana]). There are numerous false-positive and false-negative results. For example, synthetic opioids, such as fentanyl, oxycodone, and methadone are usually not detected by routine opiate screening. Blood samples may be saved for possible quantitative testing, but blood is not generally used for screening purposes since it is relatively insensitive for many common drugs, including psychotropic agents, opioids, and stimulants.

Abdominal Radiographs

A plain film of the abdomen may reveal radiopaque iron tablets, drug-filled condoms, or other toxic material. Studies suggest that few tablets are predictably visible (eg, ferrous sulfate, sodium chloride, calcium carbonate, and potassium chloride). Thus, the radiograph is useful only if abnormal.

When to Refer

Consultation with a regional poison control center (1-800-222-1222) or medical toxicologist is recommended when the diagnosis is uncertain; there are questions about what laboratory tests to order; dialysis is being considered to remove the drug or poison; or advice is needed regarding the indications, dose, and side effects of antidotes.

When to Admit

- The patient has symptoms and signs of intoxication that are not expected to clear within a 6-8 hour

observation period.
- Delayed absorption of the drug might be predicted to cause a later onset of serious symptoms (eg, after ingestion of a sustained-release product).
- Continued administration of an antidote is required (eg, *N*-acetylcysteine for acetaminophen overdose).
- Psychiatric or social services evaluation is needed for suicide attempt or suspected drug abuse.

Acetaminophen

Acetaminophen (paracetamol in the United Kingdom, Europe) is a common analgesic found in many nonprescription and prescription products. After absorption, it is metabolized mainly by glucuronidation and sulfation, with a small fraction metabolized via the P450 mixed-function oxidase system (2E1) to a highly toxic reactive intermediate. This toxic intermediate is normally detoxified by cellular glutathione. With acute acetaminophen overdose (> 150–200 mg/kg, or 8–10 g in an average adult), hepatocellular glutathione is depleted and the reactive intermediate attacks other cell proteins, causing necrosis. Patients with enhanced P450 2E1 activity, such as chronic alcoholics and patients taking INH, are at increased risk of developing hepatotoxicity. Hepatic toxicity may also occur after long-term overuse of acetaminophen—eg, as a result of taking two or three acetaminophen-containing products concurrently or exceeding the recommended maximum dose of 4 g/d for several days.

Clinical Findings

Shortly after ingestion, patients may have nausea or vomiting, but there are usually no other signs of toxicity until 24–48 hours after ingestion, when hepatic aminotransferase levels begin to increase. With severe poisoning, fulminant hepatic necrosis may occur, resulting in jaundice, hepatic encephalopathy, advanced chronic kidney disease, and death. Rarely, massive ingestion (eg, serum levels over 500–1000 mg/L) can cause early onset of acute coma, hypotension, and metabolic acidosis unrelated to hepatic injury.

The diagnosis after acute overdose is based on measurement of the serum acetaminophen level. Plot the serum level versus the time since ingestion on the acetaminophen nomogram shown in Figure 38–1: illustration. Ingestion of sustained-release products or coingestion of an anticholinergic agent, salicylate, or opioid drug may cause delayed elevation of serum levels and may render the nomogram useless. The nomogram is not useful after chronic overdose.

Figure 38–1

Nomogram for prediction of acetaminophen hepatotoxicity following acute overdosage. The upper line defines serum acetaminophen concentrations associated with a risk of hepatotoxicity; the lower line defines serum levels 25% below those expected to cause hepatotoxicity. In uncomplicated cases, the upper line is usually used as an indication for therapy with *N*-acetylcysteine. However, to provide a margin for error in the estimation of the time of ingestion and for patients at higher risk for hepatotoxicity, the lower line is often used as a guide to treatment. (Adapted, with permission, from Rumack BH et al. Acetaminophen poisoning and toxicity. Pediatrics. 1975 Jun;55(6):871–6.)

Treatment

Emergency and Supportive Measures

Administer activated charcoal (see Antidotes & Other Treatment-Activated Charcoal) if it can be given within 1–2 hours of the ingestion. Although charcoal may interfere with absorption of the oral antidote acetylcysteine, this is not considered clinically significant.

Specific Treatment

Although the general recommendation is to treat if the serum acetaminophen level is above the toxic line on the nomogram (Figure 38–1: illustration), many clinicians and published guidelines prefer to use the lower line as a guide to treatment, as it provides a 25% safety margin. If the precise time of ingestion is unknown or if the patient is at higher risk for hepatotoxicity (eg, alcoholic, liver disease, long-term use of P450-inducing drugs), then use a lower threshold for initiation of *N*-acetylcysteine (in some case reports, a level of 100 mg/L at 4 hours was suggested in very high-risk patients).

The antidote *N*-acetylcysteine can be given orally or intravenously. Oral treatment begins with a loading dose of *N*-acetylcysteine, 140 mg/kg, followed by 70 mg/kg every 4 hours. Dilute the solution to 5% with water, juice, or soda. If vomiting interferes with oral *N*-acetylcysteine administration, consider giving the antidote intravenously (see below). The most widely used oral *N*-acetylcysteine protocol in the United States calls for 72 hours of treatment. However, other regimens have demonstrated equivalent success with 20–48 hours of treatment.

A 20-hour intravenous regimen was recently approved by the FDA (Acetadote). It calls for a loading dose of 150 mg/kg given intravenously over 60 minutes, followed by a 4-hour infusion of 50 mg/kg, and a 16-hour infusion of 100 mg/kg. (If Acetadote is not available, the conventional oral formulation may also be given intravenously using a micropore filter and a slow rate of infusion. Call a regional poison control center or medical toxicologist for assistance.)

Treatment with *N*-acetylcysteine is most effective if it is started within 8–10 hours after ingestion.

the treatment of acetaminophen poisoning. Am J Health Syst Pharm. 2006 Oct 1;63(19):1821–7. [PMID: 16990628]

Acids, Corrosive

The strong mineral acids exert primarily a local corrosive effect on the skin and mucous membranes. Symptoms include severe pain in the throat and upper gastrointestinal tract; bloody vomitus; difficulty in swallowing, breathing, and speaking; discoloration and destruction of skin and mucous membranes in and around the mouth; and shock. Severe systemic metabolic acidosis may occur both as a result of cellular injury and from systemic absorption of the acid.

Severe deep destructive tissue damage may occur after exposure to hydrofluoric acid because of the penetrating and highly toxic fluoride ion. Systemic hypocalcemia and hyperkalemia may also occur after fluoride absorption, even following skin exposure.

Inhalation of volatile acids, fumes, or gases such as chlorine, fluorine, bromine, or iodine causes severe irritation of the throat and larynx and may cause upper airway obstruction and noncardiogenic pulmonary edema.

Treatment

Ingestion

Dilute immediately by giving a glass (4–8 oz) of water to drink. Do *not* give bicarbonate or other neutralizing agents, and do *not* induce vomiting. Some experts recommend immediate placement of a small flexible gastric tube and removal of stomach contents followed by lavage, particularly if the corrosive is a liquid or has important systemic toxicity.

In symptomatic patients, perform flexible endoscopic esophagoscopy to determine the presence and extent of injury. CT scan or plain radiographs of the chest and abdomen may reveal esophageal or gastric perforation. Perforation, peritonitis, and major bleeding are indications for surgery.

Skin Contact

Flood with water for 15 minutes. Use no chemical antidotes; the heat of the reaction may cause additional injury.

For hydrofluoric acid burns, soak the affected area in benzalkonium chloride solution or apply 2.5% calcium gluconate gel (prepared by adding 3.5 g calcium gluconate to 5 oz of water-soluble surgical lubricant, eg, K-Y Jelly); then arrange immediate consultation with a plastic surgeon or other specialist. Binding of the fluoride ion may be achieved by injecting 0.5 mL of 5% calcium gluconate per square centimeter under the burned area.

(**Caution:** *Do not use calcium chloride.*) Intra-arterial infusion of calcium is sometimes required for extensive burns or those involving the nail bed; consult with a hand surgeon or poison control center (1-800-222-1222).

Eye Contact

Anesthetize the conjunctiva and corneal surfaces with topical local anesthetic drops (eg, proparacaine). Flood with water for 15 minutes, holding the eyelids open. Check pH with pH 6.0–8.0 test paper, and repeat irrigation, using 0.9% saline, until pH is near 7.0. Check for corneal damage with fluorescein and slit lamp examination; consult an ophthalmologist about further treatment.

Inhalation

Remove from further exposure to fumes or gas. Check skin and clothing. Treat pulmonary edema.

Vohra R et al. Recurrent life-threatening ventricular dysrhythmias associated with acute hydrofluoric acid ingestion: observations in one case and implications for mechanism of toxicity. Clin Toxicol (Phila). 2008

Jan;46(1):79–84. [PMID: 17906993]

Alkalies

The strong alkalies are common ingredients of some household cleaning compounds and may be suspected by their "soapy" texture. Those with alkalinity above pH 12.0 are particularly corrosive. Disk (or "button") batteries are also a source. Alkalies cause liquefactive necrosis, which is deeply penetrating. Symptoms include burning pain in the upper gastrointestinal tract, nausea, vomiting, and difficulty in swallowing and breathing. Examination reveals destruction and edema of the affected skin and mucous membranes and bloody vomitus and stools. Radiographs may reveal evidence of perforation or the presence of radiopaque disk batteries in the esophagus or lower gastrointestinal tract.

Treatment

Ingestion

Dilute immediately with a glass of water. Do *not* induce emesis. Some gastroenterologists recommend immediate placement of a small flexible gastric tube and removal of stomach contents followed by gastric lavage after ingestion of liquid caustic substances to remove residual material.

Prompt endoscopy is recommended in symptomatic patients to evaluate the extent of damage. If radiograph reveals the location of ingested disk batteries in the esophagus, immediate endoscopic removal is mandatory.

The use of corticosteroids to prevent stricture formation is of no proved benefit and is definitely contraindicated if there is evidence of esophageal perforation.

Skin Contact

Wash with running water until the skin no longer feels soapy. Relieve pain and treat shock.

Eye Contact

Anesthetize the conjunctival and corneal surfaces with topical anesthetic (eg, proparacaine). Irrigate with water or saline continuously for 20–30 minutes, holding the lids open. Check pH with pH test paper, and repeat irrigation, using 0.9% saline, for additional 30-minute periods until the pH is near 7.0. Check for corneal damage with fluorescein and slit lamp examination; consult an ophthalmologist for further treatment.

Amphetamines & Cocaine

Amphetamines and cocaine are widely abused for their euphorigenic and stimulant properties. Both drugs may be smoked, snorted, ingested, or injected. Amphetamines and cocaine produce central nervous system stimulation and a generalized increase in central and peripheral sympathetic activity. The toxic dose of each drug is highly variable and depends on the route of administration and individual tolerance. The onset of effects is most rapid after intravenous injection or smoking. Amphetamine derivatives and related drugs include methamphetamine ("crystal meth," "crank"), MDMA ("Ecstasy"), ephedrine ("herbal ecstasy"), and methcathinone ("cat"). Nonprescription medications and nutritional supplements may contain stimulant or sympathomimetic drugs such as ephedrine, yohimbine, or caffeine (see Theophylline).

Clinical Findings

Presenting symptoms may include anxiety, tremulousness, tachycardia, hypertension, diaphoresis, dilated pupils, agitation, muscular hyperactivity, and psychosis. Muscle hyperactivity may lead to metabolic acidosis and rhabdomyolysis. In severe intoxication, seizures and hyperthermia may occur. Sustained or severe hypertension may result in intracranial hemorrhage, aortic dissection, or myocardial infarction. Hyponatremia has been reported after MDMA use; the mechanism is not known but may involve excessive water intake, syndrome of inappropriate antidiuretic hormone (SIADH), or both.

The diagnosis is supported by finding amphetamines, cocaine, or the cocaine metabolite benzoylecgonine in the urine. Blood screening is generally not sensitive enough to detect these drugs.

Treatment

Emergency and Supportive Measures

Maintain a patent airway and assist ventilation, if necessary. Treat coma or seizures as described at the beginning of this chapter. Rapidly lower the body temperature (see Hyperthermia, above) in patients who are hyperthermic (temperature > 39–40 °C).

Specific Treatment

Treat agitation, psychosis, or seizures with a benzodiazepine such as lorazepam, 2–3 mg intravenously. Add phenobarbital 15 mg/kg intravenously for persistent seizures. Treat hypertension with a vasodilator drug such as phentolamine (1–5 mg intravenously) or a combined - and -adrenergic blocker such as labetalol (10–20 mg intravenously). Do *not* administer a pure -blocker such as propranolol alone, as this may result in paradoxic worsening of the hypertension as a result of unopposed -adrenergic effects.

Treat tachycardia or tachyarrhythmias with a short-acting -blocker such as esmolol (25–100 mcg/kg/min by intravenous infusion). Treat hyperthermia as described above. Treat hyponatremia as outlined in Chapter 21: Fluid & Electrolyte Disorders.

Anticoagulants

Warfarin and related compounds (including ingredients of many commercial rodenticides) inhibit the clotting mechanism by blocking hepatic synthesis of vitamin K-dependent clotting factors.

Anticoagulants may cause hemoptysis, gross hematuria, bloody stools, hemorrhages into organs, widespread bruising, and bleeding into joint spaces. The prothrombin time is increased within 12–24 hours (peak 36–48 hours) after a single overdose. After ingestion of brodifacoum, difenacoum, and related rodenticides (so-called "superwarfarins"), inhibition of clotting factor synthesis may persist for several weeks or even months after a single dose.

Treatment

Emergency and Supportive Measures

Discontinue the drug at the first sign of gross bleeding, and determine the prothrombin time (international normalized ratio, INR). If the patient has ingested an acute overdose, administer activated charcoal (see Antidotes & Other Treatment-Activated Charcoal).

Specific Treatment

Do *not* treat prophylactically with vitamin K—wait for the evidence of anticoagulation (elevated prothrombin time). If the INR is elevated, give phytonadione (vitamin K1), 10–25 mg orally, and additional doses as needed to restore the prothrombin time to normal. Doses as high as 200 mg/d have been required after ingestion of "superwarfarins." Give fresh-frozen plasma or activated Factor VII as needed to rapidly correct the coagulation factor deficit if there is serious bleeding. If the patient is chronically anticoagulated and has strong medical indications for being maintained in that status (eg, prosthetic heart valve), give much smaller doses of vitamin K (1 mg orally) and fresh-frozen plasma (or both) to titrate to the desired prothrombin time.

If the patient has ingested brodifacoum or a related superwarfarin, prolonged observation (over weeks) and repeated administration of large doses of vitamin K may be required.

Anticonvulsants

Anticonvulsants (carbamazepine, phenytoin, valproic acid, and many newer agents) are widely used in the management of seizure disorders. In addition, carbamazepine and valproic acid are increasingly used for treatment of mood disorders.

Phenytoin can be given orally or intravenously. Rapid intravenous injection of phenytoin can cause acute myocardial depression and cardiac arrest owing to the solvent propylene glycol (fosphenytoin does not contain this diluent). Chronic phenytoin intoxication can occur following only slightly increased doses because of zero-order kinetics and a small toxic-therapeutic window. Phenytoin intoxication can also occur following acute intentional or accidental overdose. The overdose syndrome is usually mild even with high serum levels. The most common manifestations are ataxia, nystagmus, and drowsiness. Choreoathetoid movements have been described.

Carbamazepine is used for treatment of trigeminal neuralgia, temporal lobe epilepsy, and other seizure disorders. Intoxication causes drowsiness, stupor and, with high levels, coma and seizures. Dilated pupils and tachycardia are common. Toxicity may be seen with serum levels greater than 20 mg/L, though severe poisoning is usually associated with concentrations greater than 30–40 mg/L. Because of erratic and slow absorption, intoxication may progress over several hours to days.

Valproic acid intoxication produces a unique syndrome consisting of hypernatremia (from the sodium component of the salt), metabolic acidosis, hypocalcemia, elevated serum ammonia, and mild liver aminotransferase elevation. Hypoglycemia may occur as a result of hepatic metabolic dysfunction. Coma with small pupils may be seen and can mimic opioid poisoning. Encephalopathy and cerebral edema can occur.

The newer anticonvulsants **gabapentin**, **levetiracetam**, **vigabatrin,** and **zonisamide** generally cause somnolence, confusion and dizziness; **felbamate** can cause crystalluria and kidney dysfunction after overdose, and may cause idiosyncratic aplastic anemia with therapeutic use; **lamotrigine, topiramate,** and **tiagabine** have been reported to cause seizures after overdose.

Treatment

Emergency and Supportive Measures

For recent ingestions, give activated charcoal orally or by gastric tube. For large ingestions of carbamazepine or valproic acid—especially of sustained-release formulations—consider whole bowel irrigation (see Antidotes & Other Treatment-Whole Bowel Irrigation). Multiple-dose activated charcoal and whole-bowel irrigation may be beneficial in ensuring gut decontamination for selected large ingestions.

Specific Treatment

There are no specific antidotes. Naloxone was reported to have reversed valproic acid overdose in one anecdotal case. Carnitine may be useful in patients with valproic acid–induced hyperammonemia. Consider hemodialysis for massive intoxication with valproic acid or carbamazepine (eg, carbamazepine levels > 60 mg/L or valproic acid levels > 800 mg/L).

Arsenic

Arsenic is found in some pesticides and industrial chemicals, and arsenic trioxide has recently been reintroduced as a chemotherapeutic agent. A massive epidemic of chronic arsenic poisoning has occurred in Bangladesh due to naturally occurring arsenic in deep aquifers. Symptoms of acute poisoning usually appear within 1 hour after ingestion but may be delayed as long as 12 hours. They include abdominal pain, vomiting, watery diarrhea, and skeletal muscle cramps. Profound dehydration and shock may occur. In chronic poisoning, symptoms can be vague but often include pancytopenia, painful peripheral sensory neuropathy, and skin changes including melanosis, keratosis, and desquamating rash. Urinary arsenic levels may be falsely elevated after certain meals (eg, seafood) that contain large quantities of a nontoxic form of organic arsenic.

Treatment

Emergency Measures

After recent ingestion (within 1–2 hours), perform gastric lavage and administer 60–100 g of activated charcoal (see Antidotes & Other Treatment-Activated Charcoal). Administer intravenous fluids to replace losses due to vomiting and diarrhea

Antidote

For patients with severe acute intoxication, give dimercaprol injection (British anti-Lewisite, BAL), 10% solution in oil, 3–5 mg/kg intramuscularly every 4–6 hours for 2 days. The side effects include nausea, vomiting, headache, and hypertension. Follow dimercaprol with oral succimer (dimercaptosuccinic acid, DMSA), 10 mg/kg every 8 hours, for 1 week. Consult a medical toxicologist or regional poison control center (800-222-1222) for advice regarding chelation.

Khandpur S et al. Chronic arsenic toxicity from Ayurvedic medicines. Int J Dermatol. 2008 Jun;47(6):618–21. [PMID: 18477160]

Atropine & Anticholinergics

Atropine, scopolamine, belladonna, diphenoxylate with atropine, *Datura stramonium*, *Hyoscyamus niger*, some mushrooms, tricyclic antidepressants, and antihistamines are antimuscarinic agents with variable central nervous system effects. The patient complains of dryness of the mouth, thirst, difficulty in swallowing, and blurring of vision. The physical signs include dilated pupils, flushed skin, tachycardia, fever, delirium, myoclonus, ileus, and flushed appearance. Antidepressants and antihistamines may induce convulsions.

Antihistamines are commonly available with or without prescription. Diphenhydramine commonly causes delirium, tachycardia, and seizures. Massive overdose may mimic tricyclic antidepressant poisoning.

Treatment

Emergency and Supportive Measures

Administer activated charcoal (see Antidotes & Other Treatment: Activated Charcoal). Tepid sponge baths and sedation, or neuromuscular paralysis in rare cases, are indicated to control high temperatures (see The Symptomatic Patient: Hyperthermia: Treatment).

Specific Treatment

For pure atropine or related anticholinergic syndrome, if symptoms are severe (eg, agitated delirium or excessively rapid tachycardia), give physostigmine salicylate, 0.5–1 mg slowly intravenously over 5 minutes, with ECG monitoring; repeat as neeed to a total dose of 2 mg. Bradyarrhythmias and convulsions are a hazard with physostigmine administration, and it should be avoided in patients with tricyclic antidepressant overdose.

Pragst F et al. Poisonings with diphenhydramine—a survey of 68 clinical and 55 death cases. Forensic Sci Int. 2006 Sep 12;161(2–3):189–97. [PMID: 16857332]

Spina SP et al. Teenagers with Jimson weed (*Datura stramonium*) poisoning. CJEM. 2007 Nov;9(6):467–8. [PMID: 18072995]

-Adrenergic Blockers

There are a wide variety of -adrenergic blocking drugs, with varying pharmacologic and pharmacokinetic properties (see Table 11–7). The most toxic -blocker is propranolol. Propranolol competitively blocks $_1$ and $_2$ adrenoceptors and also has direct membrane-depressant and central nervous system effects.

Clinical Findings

The most common findings with mild or moderate intoxication are hypotension and bradycardia. Cardiac depression from more severe poisoning is often unresponsive to conventional therapy with -adrenergic stimulants such as dopamine and norepinephrine. In addition, with propranolol and other lipid-soluble drugs, seizures and coma may occur. Propranolol, oxprenolol, acebutolol, and alprenolol also have membrane-depressant effects and can cause conduction disturbance (wide QRS interval) similar to tricyclic antidepressant overdose.

The diagnosis is based on typical clinical findings. Routine toxicology screening does not usually include -blockers.

Treatment

Emergency and Supportive Measures

Initially, treat bradycardia or heart block with atropine (0.5–2 mg intravenously), isoproterenol (2–20 mcg/min by intravenous infusion, titrated to the desired heart rate), or an external transcutaneous cardiac pacemaker. However, these measures are often ineffective, and specific antidotal treatment may be necessary (see below).

For ingested drugs, administer activated charcoal (see Antidotes & Other Treatment-Activated Charcoal).

Specific Treatment

If the above measures are not successful in reversing bradycardia and hypotension, give glucagon, 5–10 mg intravenously, followed by an infusion of 1–5 mg/h. Glucagon is an inotropic agent that acts at a different receptor site and is therefore not affected by -blockade. Membrane-depressant effects (wide QRS interval) may respond to boluses of sodium bicarbonate (50–100 mEq intravenously) as for tricyclic antidepressant poisoning.

Kerns W 2nd. Management of beta-adrenergic blocker and calcium channel antagonist toxicity. Emerg Med Clin North Am. 2007 May;25(2):309–31. [PMID: 17482022]

Shepherd G. Treatment of poisoning caused by beta-adrenergic and calcium-channel blockers. Am J Health Syst Pharm. 2006 Oct 1;63(19):1828–35. [PMID: 16990629]

Calcium Channel Blockers

Calcium channel blockers are used to treat angina pectoris, hypertension, supraventricular tachycardia, migraine, and other disorders. In therapeutic doses, nifedipine, nicardipine, amlodipine, felodipine, isradipine, nisoldipine, and nimodipine act mainly on blood vessels, while verapamil and diltiazem act mainly on cardiac contractility and conduction. However, these selective effects are lost after acute overdose. Patients may present with bradycardia, atrioventricular (AV) nodal block, hypotension, or a combination of these effects. Hyperglycemia is common due to blockade of insulin release. With severe poisoning, cardiac arrest may occur.

Treatment

Emergency and Supportive Measures

For ingested drugs, administer activated charcoal (see Antidotes & Other Treatment-Activated Charcoal). In addition, whole bowel irrigation should be initiated as soon as possible if the patient has ingested a sustained-release product.

Specific Treatment

If bradycardia and hypotension are not reversed with atropine (0.5–2 mg intravenously), isoproterenol (2–20 mcg/min by intravenous infusion), or a transcutaneous cardiac pacemaker, administer calcium chloride intravenously. Start with calcium chloride 10%, 10 mL, or calcium gluconate 10%, 20 mL. Repeat the dose every 3–5 minutes. The optimum (or maximum) dose has not been established, but there are reports of success after as much as 10–12 g of calcium chloride. Calcium is most useful in reversing negative inotropic effects and is less effective for AV nodal blockade and bradycardia. Epinephrine infusion (1–4 mcg/min initially) and glucagon (5–10 mg intravenously) have also been recommended. In addition, high doses of insulin (0.5–1 units/kg intravenous bolus followed by 0.5–1 units/kg/h infusion) along with sufficient dextrose to maintain euglycemia have been reported to be beneficial but there are no controlled studies. Infusion of Intralipid 20% lipid emulsion has been reported to improve hemodynamics in an animal model of verapamil poisoning.

Bania TC et al. Hemodynamic effects of intravenous fat emulsion in an animal model of severe verapamil toxicity resuscitated with atropine, calcium, and saline. Acad Emerg Med. 2007 Feb;14(2):105–11. [PMID: 17267527]

Carbon Monoxide

Carbon monoxide is a colorless, odorless gas produced by the combustion of carbon-containing materials. Poisoning may occur as a result of suicidal or accidental exposure to automobile exhaust, smoke inhalation in a fire, or accidental exposure to an improperly vented gas heater or other appliance. Carbon monoxide avidly binds to hemoglobin, with an affinity approximately 250 times that of oxygen. This results in reduced oxygen-carrying capacity and altered delivery of oxygen to cells (see also Smoke Inhalation in Pulmonology).

Clinical Findings

At low carbon monoxide levels (carboxyhemoglobin saturation 10–20%), victims may have headache, dizziness, abdominal pain, and nausea. With higher levels, confusion, dyspnea, and syncope may occur. Hypotension, coma, and seizures are common with levels greater than 50–60%. Survivors of acute severe poisoning may develop permanent obvious or subtle neurologic and neuropsychiatric deficits. The fetus and newborn may be more susceptible because of high carbon monoxide affinity for fetal hemoglobin.

Carbon monoxide poisoning should be suspected in any person with severe headache or acutely altered mental status, especially during cold weather, when improperly vented heating systems may have been used. Diagnosis depends on specific measurement of the arterial or venous carboxyhemoglobin saturation, although the level may have declined if high-flow oxygen therapy has already been administered, and levels do not always correlate with clinical symptoms. Routine arterial blood gas testing and pulse oximetry are not useful because they give falsely normal PaO_2 and oxyhemoglobin saturation determinations, respectively. (A newer pulse oximetry device, the pulse CO-oximeter [Masimo Rad-57] is capable of distinguishing oxyhemoglobin from carboxyhemoglobin.)

Treatment

Emergency and Supportive Measures

Maintain a patent airway and assist ventilation, if necessary. Remove the victim from exposure. Treat patients with coma, hypotension, or seizures as described at the beginning of this chapter.

Specific Treatment

The half-life of the carboxyhemoglobin (CoHb) complex is about 4–5 hours in room air but is reduced dramatically by high concentrations of oxygen. Administer 100%

oxygen by tight-fitting high-flow reservoir face mask or endotracheal tube. Hyperbaric oxygen (HBO) can provide 100% oxygen under higher than atmospheric pressures, further shortening the half-life; it may also reduce the incidence of subtle neuropsychiatric sequelae. Recent studies disagree about the benefit of HBO, but generally recommended indications for HBO in patients with carbon monoxide poisoning include a history of loss of consciousness, CoHb greater than 25%, metabolic acidosis, age over 50 years, and cerebellar findings on neurologic examination.

Chemical Warfare: Nerve Agents

Nerve agents used in chemical warfare work by cholinesterase inhibition and are most commonly organophosphorus compounds. Agents such as **tabun** (GA), **sarin** (GB), **soman** (GD), and **VX** are similar to insecticides such as malathion but are vastly more potent. They may be inhaled or absorbed through the skin. Systemic effects due to unopposed action of acetylcholine include miosis, salivation, abdominal cramps, diarrhea, and muscle paralysis producing respiratory arrest. Inhalation also produces severe bronchoconstriction and copious nasal and tracheobronchial secretions.

Treatment

Emergency and Supportive Measures

Perform thorough decontamination of exposed areas with repeated soap and shampoo washing. Personnel caring for such patients must wear protective clothing and gloves, since cutaneous absorption may occur through normal skin.

Specific Treatment

Give atropine in an initial dose of 2 mg intravenously, and repeat as needed to reverse signs of acetylcholine excess. (Some victims have required several hundred milligrams.) Treat also with the cholinesterase-reactivating agent pralidoxime, 1–2 g intravenously initially followed by an infusion at a rate of 200–400 mg/h. United States military personnel in the Iraq invasion were equipped with autoinjectable units containing 2 mg of atropine plus 600 mg of the cholinesterase-reactivating agent pralidoxime.

Yoshida T. Preparedness response to hazard and toxic incidents and food terrorism. Yakugaku Zasshi. 2008 Jun;128(6):851–7. [PMID: 18520132]

Chemical Warfare: Ricin

Ricin is a naturally occurring toxin found in minute quantities in the castor bean (*Ricinus communis*). It can cause toxicity if castor beans are thoroughly chewed or blenderized, although the quantity of ricin is small and it is poorly absorbed from the gastrointestinal tract, so symptoms following castor bean ingestion are usually limited to diarrhea and abdominal pain. Less commonly, severe gastroenteritis can lead to volume depletion and advanced chronic kidney disease. On the other hand, purified ricin is extremely toxic if administered parenterally: the LD_{50} for injected ricin in animals is as low as 0.1 mcg/kg. A fatal case of suspected ricin poisoning by homicidal injection of an estimated 0.28 mg of ricin was associated with diffuse organ damage and death from cardiac failure after 2 days. Inhalation of ricin powder has not been reported in humans, but animal studies suggest it could cause hemorrhagic tracheobronchitis and pneumonia.

Treatment

Emergency and Supportive Measures

After suspected ricin inhalation or exposure to powdered ricin, remove clothing and wash skin with water. Personnel caring for such patients should wear protective respiratory gear, clothing, and gloves.

Specific Treatment

There is no known antidote or other specific treatment. A vaccine has been developed and is undergoing clinical trials. Provide supportive care for volume loss due to gastroenteritis and cardiac and respiratory support as needed.

Schier JG et al. Public health investigation after the discovery of ricin in a South Carolina postal facility. Am J Public Health. 2007 Apr;97(Suppl 1):S152–7. [PMID: 17413057]

Chlorinated Insecticides

Lindane (Kwell) and other chlorinated insecticides (chlorophenothane [DDT], lindane, toxaphene, chlordane, aldrin, endrin) are central nervous system stimulants that can cause poisoning by ingestion, inhalation, or direct contact. Most of these agents have been removed from the United States market because of their acute toxicity and their potential to accumulate in the food chain. The estimated lethal dose is about 20 g for DDT, 3 g for lindane, 2 g for toxaphene, 1 g for chlordane, and less than 1 g for endrin and aldrin. The manifestations of poisoning are nervous irritability, muscle twitching, seizures, and coma. Arrhythmias may occur. Hepatic and renal damage are reported.

Treatment

Give activated charcoal (see Antidotes & Other Treatment-Activated Charcoal) and consider gastric lavage for large recent ingestions (see Antidotes & Other Treatment-Gastric Lavage). Repeat-dose activated charcoal may be effective for large ingestions. For seizures, give diazepam, 5–10 mg slowly intravenously, or other anticonvulsants as described in The Symptomatic Patient: Seizures: Treatment.

Perform thorough decontamination of exposed areas with repeated soap and shampoo washing. Personnel caring for such patients must wear protective clothing and gloves, since cutaneous absorption may occur through normal skin.

Singal A et al. Lindane neurotoxicity in childhood. Am J Ther. 2006 May–Jun;13(3):277–80. [PMID: 16772770]

Clonidine & Other Sympatholytic Antihypertensives

Overdosage with these agents (clonidine, guanabenz, guanfacine, methyldopa) causes bradycardia, hypotension, miosis, respiratory depression, and coma. (Transient hypertension occasionally occurs after acute overdosage, a result of peripheral -adrenergic effects in high doses.) Symptoms are usually resolved in less than 24 hours, and deaths are rare. Similar symptoms may occur after ingestion of topical nasal decongestants chemically similar to clonidine (oxymetazoline, tetrahydrozoline, naphazoline). Brimonidine is used as an ophthalmic preparation for glaucoma. Tizanidine is a centrally acting muscle relaxant structurally related to clonidine; it produces similar toxicity in overdose.

Treatment

Emergency and Supportive Measures

Give activated charcoal (see Antidotes & Other Treatment-Activated Charcoal). Maintain the airway and support respiration if necessary. Symptomatic treatment is usually sufficient even in massive overdose. Maintain blood pressure with intravenous fluids. Dopamine can also be used. Atropine is usually effective for bradycardia.

Specific Treatment

There is no specific antidote. Although tolazoline has been recommended for clonidine overdose, its effects are unpredictable and it should not be used. Naloxone has been reported to be successful in a few anecdotal and poorly substantiated cases.

Sklerov JH et al. Tizanidine distribution in a postmortem case. J Anal Toxicol. 2006 Jun;30(5):331–4. [PMID: 16839471]

Cocaine

See Amphetamines & Cocaine.

Cyanide

Cyanide is a highly toxic chemical used widely in research and commercial laboratories and many industries. Its gaseous form, hydrogen cyanide, is an important component of smoke in fires. Cyanide-generating glycosides are also found in the pits of apricots and other related plants. Cyanide is generated by the breakdown of nitroprusside, and poisoning can result from rapid high-dose infusions. Cyanide is also formed by metabolism of acetonitrile, a solvent found in some over-the-counter fingernail glue removers. Cyanide is rapidly absorbed by inhalation, skin absorption, or ingestion. It disrupts cellular function by inhibiting cytochrome oxidase and preventing cellular oxygen utilization.

Clinical Findings

The onset of toxicity is nearly instantaneous after inhalation of hydrogen cyanide gas but may be delayed for minutes to hours after ingestion of cyanide salts or cyanogenic plants or chemicals. Effects include headache, dizziness, nausea, abdominal pain, and anxiety, followed by confusion, syncope, shock, seizures, coma, and death. The odor of "bitter almonds" may be detected on the victim's breath or in vomitus, though this is not a reliable finding. The venous oxygen saturation may be elevated (> 90%) in severe poisonings because tissues have failed to take up arterial oxygen.

Treatment

Emergency and Supportive Measures

Remove the victim from exposure, taking care to avoid exposure to rescuers. For suspected cyanide poisoning due to nitroprusside infusion, stop or slow the rate of infusion. (Metabolic acidosis and other signs of cyanide poisoning usually clear rapidly.)

For cyanide ingestion, administer activated charcoal (see Antidotes & Other Treatment-Activated Charcoal). Although charcoal has a low affinity for cyanide, the usual doses of 60–100 g are adequate to bind typically ingested lethal doses (100–200 mg).

Specific Treatment

In the United States, the conventional cyanide antidote package (Taylor Pharmaceuticals) (Table 38–7) contains nitrites (to induce methemoglobinemia, which binds free cyanide) and thiosulfate (to promote conversion of cyanide to the less toxic thiocyanate). Administer amyl nitrite by crushing an ampule under the victim's nose or at the end of the endotracheal tube, and administer 3% sodium nitrite solution, 10 mL intravenously. **Caution:** Nitrites may induce hypotension and dangerous levels of methemoglobin. Also administer 25%sodium thiosulfate solution, 50 mL intravenously (12.5 g). Hydroxocobalamin, a newer and potentially safer alternative antidote, was approved by the FDA in December 2006. The dose of hydroxocobalamin (Cyanokit, EMD Pharmaceuticals) is 5 g intravenously (children, 70 mg/kg).

Table 38–7. Currently available (prepackaged) cyanide antidotes.

Antidote	**Contents**	**Action**
Conventional cyanide antidote kit[1]	Amyl nitrite, 0.3 mL aspirol for inhalation; sodium	Nitrites induce methemoglobinemia, which binds CN;

	nitrite 300 mg in a 10-mL vial; sodium thiosulfate 12.5 g in a 50-mL vial	thiosulfate hastens CN conversion to less toxic thiocyanate
Cyanokit[2]	Hydroxocobalamin 5 g in two 2.5-g vials	Converts CN to cyanocobalamin (vitamin B12)

[1] In the United States, manufactured by Taylor Pharmaceuticals.

[2] Manufactured by EMD Pharmaceuticals.

Digitalis & Other Cardiac Glycosides

Cardiac glycosides are derived from a variety of plants and are widely used to treat heart failure and supraventricular arrhythmias. These drugs paralyze the

Na^+-K^+-ATPase pump and have potent vagotonic effects. Intracellular effects include enhancement of calcium-dependent contractility and shortening of the action potential duration. Digoxin and ouabain are highly tissue-bound, but digitoxin has a volume of distribution of just 0.6 L/kg, making it potentially accessible to enhanced removal procedures such as hemoperfusion or repeated doses of activated charcoal. There are a number of plants (eg, oleander, foxglove, lily-of-the-valley) that contain cardiac glycosides. Bufotenin, a cardiotoxic steroid found in certain toad secretions and used as an herbal medicine and a purported aphrodisiac, has pharmacologic properties similar to cardiac glycosides.

Clinical Findings

Intoxication may result from acute single exposure or chronic accidental overmedication. After acute overdosage, nausea and vomiting, bradycardia, hyperkalemia, and AV block frequently occur. Patients in whom toxicity develops gradually during long-term therapy may be hypokalemic and hypomagnesemic owing to concurrent diuretic treatment and more commonly present with ventricular arrhythmias (eg, ectopy, bidirectional ventricular tachycardia, or ventricular fibrillation). Digoxin levels may be only slightly elevated in patients with intoxication from cardiac glycosides other than digoxin because of limited cross-reactivity of immunologic tests.

Treatment

Emergency and Supportive Measures

After acute ingestion, administer activated charcoal (see Antidotes & Other Treatment-Activated Charcoal). Monitor potassium levels and cardiac rhythm closely. Treat bradycardia initially with atropine (0.5–2 mg intravenously) or a transcutaneous external cardiac pacemaker.

Specific Treatment

For patients with significant intoxication, administer digoxin-specific antibodies (digoxin immune Fab [ovine]; Digibind or DigiFab). Estimation of the Digibind dose is based on the body burden of digoxin calculated from the ingested dose or the steady-state serum digoxin concentration:

From the ingested dose

Number of vials = approximately 1.5–2 x ingested dose (mg).

From the serum concentration

Number of vials = serum digoxin (ng/mL) x body weight (kg) x 10^{-2}. **Note:** This is based on the equilibrium digoxin level; after acute overdose, serum levels are falsely high before tissue distribution is complete, and overestimation of the Digibind or DigiFab dose is likely.

Empiric dosing

Empiric dosing of Digibind or DigiFab may be used if the patient's condition is relatively stable and an underlying condition (eg, atrial fibrillation) suggests a residual level of digitalis activity. Start with one or two vials and reassess the clinical condition after 20–30 minutes. For cardiac glycosides other than digoxin or digitoxin, there is no formula for estimation of vials needed and treatment is empiric.

Note: After administration of digoxin-specific Fab antibody fragment, serum digoxin levels may be falsely elevated depending on the assay technique.

(Phila). 2008 Apr;46(4):340–1. [PMID: 18363136]

Ethanol, Benzodiazepines, & Other Sedative-Hypnotic Agents

The group of agents known as sedative-hypnotic drugs includes a variety of products used for the treatment of anxiety, depression, insomnia, and epilepsy. Ethanol and other selected agents are also popular recreational drugs. All of these drugs depress the central nervous system reticular activating system, cerebral cortex, and cerebellum.

Clinical Findings

Mild intoxication produces euphoria, slurred speech, and ataxia. Ethanol intoxication may produce hypoglycemia, even at relatively low concentrations. With more severe intoxication, stupor, coma, and respiratory arrest may occur. Carisoprodol (Soma) commonly causes muscle jerking or myoclonus. Death or serious morbidity is usually the result of pulmonary aspiration of gastric contents. Bradycardia, hypotension, and hypothermia are common. Patients with massive intoxication may appear to be dead, with no reflex responses and even absent electroencephalographic activity. Diagnosis and assessment of severity of intoxication are usually based on clinical findings. Ethanol serum levels greater than 300 mg/dL (0.3 g/dL; 65 mmol/L) can produce coma in persons who are not chronically abusing the drug, but regular users may remain awake at much higher levels. Phenobarbital levels greater than 100 mg/L usually cause coma.

Treatment

Emergency and Supportive Measures

Administer activated charcoal (see Antidotes & Other Treatment-Activated Charcoal). Repeat-dose charcoal may enhance elimination of phenobarbital, but it has not been proved to improve clinical outcome. Hemodialysis may be necessary for patients with severe phenobarbital intoxication.

Specific Treatment

Flumazenil is a benzodiazepine receptor-specific antagonist; it has no effect on ethanol, barbiturates, or other sedative-hypnotic agents. If used, flumazenil is given slowly intravenously, 0.2 mg over 30–60 seconds, repeated in 0.5 mg increments as needed up to a total dose of 3–5 mg. **Caution:** Flumazenil may induce seizures in patients with preexisting seizure disorder, benzodiazepine addiction, or concomitant tricyclic antidepressant overdose. If seizures occur, diazepam and other benzodiazepine anticonvulsants will not be effective. As with naloxone, the duration of action of flumazenil is short (2–3 hours) and resedation may occur, requiring repeated doses.

Chudnofsky CR. Safety and efficacy of flumazenil in reversing conscious sedation in the emergency department. Emergency Medicine Conscious Sedation Study Group. Acad Emerg Med. 1997 Oct;4(10):944–50. [PMID: 9332625]

Thomson JS et al. Use of flumazenil in benzodiazepine overdose. Emerg Med J. 2006 Feb;23(2):162. [PMID: 16439763]

-Hydroxybutyrate (GHB)

GHB has become a popular drug of abuse. It originated as a short-acting general anesthetic and is occasionally used in the treatment of narcolepsy. It gained popularity among bodybuilders for its alleged growth hormone stimulation and found its way into social settings, where it is consumed as a liquid. It has been used to facilitate sexual assault ("date-rape" drug). Symptoms after ingestion include drowsiness and lethargy followed by coma with respiratory depression. Muscle twitching and seizures are sometimes observed. Recovery is usually rapid, with patients awakening within a few hours. Other related chemicals with similar effects include butanediol and -butyrolactone (GBL). A prolonged withdrawal syndrome has been described in some heavy users.

Treatment

Monitor the airway and assist breathing if needed. There is no specific treatment. Most patients recover rapidly with supportive care. GHB withdrawal syndrome may require very large doses of benzodiazepines.

Abanades S et al. Relative abuse liability of gamma-hydroxybutyric acid, flunitrazepam, and ethanol in club drug users. J Clin Psychopharmacol. 2007 Dec;27(6):625–38. [PMID: 18004131]

Anderson IB et al. Trends in gamma-hydroxybutyrate (GHB) intoxication: 1999–2003. Ann Emerg Med. 2006 Feb;47(2):177–83. [PMID: 16431231]

Iron

Iron is widely used therapeutically for the treatment of anemia and as a daily supplement in multiple vitamin preparations. Most children's preparations contain about 12–15 mg of elemental iron (as sulfate, gluconate, or fumarate salt) per dose, compared with 60–90 mg in most adult-strength preparations. Iron is corrosive to the gastrointestinal tract and, once absorbed, has depressant effects on the myocardium and on peripheral vascular resistance. Intracellular toxic effects of iron include disruption of Krebs cycle enzymes.

Clinical Findings

Ingestion of less than 30 mg/kg of elemental iron usually produces only mild gastrointestinal upset. Ingestion of more than 40–60 mg/kg may cause vomiting (sometimes with hematemesis), diarrhea, hypotension, and acidosis. Death may occur as a result of profound hypotension due to massive fluid losses and bleeding, metabolic acidosis, peritonitis from intestinal perforation, or sepsis. Fulminant hepatic failure may occur. Survivors of the acute ingestion may suffer permanent gastrointestinal scarring.

Serum iron levels greater than 350–500 mcg/dL are considered potentially toxic, and levels over 1000 mcg/dL are usually associated with severe poisoning. A plain abdominal radiograph may reveal radiopaque tablets.

Treatment

Emergency and Supportive Measures

Treat hypotension aggressively with intravenous crystalloid solutions (0.9% saline or lactated Ringer solution). Fluid losses may be massive owing to vomiting and diarrhea as well as third-spacing into injured intestine.

Perform whole bowel irrigation (see Antidotes & Other Treatment-Whole Bowel Irrigation) to remove unabsorbed pills from the intestinal tract. Activated charcoal is not effective but may be appropriate if other ingestants are suspected.

Specific Treatment

Deferoxamine is a selective iron chelator. It is not useful as an oral binding agent. For patients with established manifestations of toxicity—and particularly those with markedly elevated serum iron levels (eg, greater than 800–1000 mcg/dL)—administer 10–15 mg/kg/h by constant intravenous infusion; higher doses (up to 40–50 mg/kg/h) have been used in massive poisonings. Hypotension may occur. The presence of an iron-deferoxamine complex in the urine may give it a "vin rosé" appearance. Deferoxamine is safe for use in pregnant women with acute iron overdose. Caution: Prolonged infusion of deferoxamine (> 36–48 hours) has been associated with development of acute respiratory distress syndrome (ARDS)— the mechanism is not known.

Ng HW et al. Endoscopic removal of iron bezoar following acute overdose. Clin Toxicol (Phila). 2008 Nov;46(9):913–5. [PMID: 18608283]

Isoniazid

INH is an antibacterial drug used mainly in the treatment and prevention of tuberculosis. It may cause hepatitis with long-term use, especially in alcoholic patients and elderly persons. It produces acute toxic effects by competing with pyridoxal 5-phosphate, resulting in lowered brain -aminobutyric acid (GABA) levels. Acute ingestion of as little as 1.5–2 g of INH can cause toxicity, and severe poisoning is likely to occur after ingestion of more than 80–100 mg/kg.

Clinical Findings

Confusion, slurred speech, and seizures may occur abruptly after acute overdose. Severe lactic acidosis—out of proportion to the severity of seizures—is probably due to inhibited metabolism of lactate. Peripheral neuropathy and acute hepatitis may occur with long-term use.

Diagnosis is based on a history of ingestion and the presence of severe acidosis associated with seizures. INH is not usually included in routine toxicologic screening, and serum levels are not readily available.

Treatment

Emergency and Supportive Measures

Seizures may require higher than usual doses of benzodiazepines (eg, lorazepam, 3–5 mg intravenously) or administration of pyridoxine as an antidote (see below).

Administer activated charcoal (see Antidotes & Other Treatment-Activated Charcoal). Do *not* induce emesis, because of the risk of abrupt onset of seizures.

Specific Treatment

Pyridoxine (vitamin B6) is a specific antagonist of the acute toxic effects of INH and is usually successful in controlling convulsions that do not respond to benzodiazepines. Give 5 g intravenously over 1–2 minutes or, if the amount ingested is known, give a gram-for-gram equivalent amount of pyridoxine. Patients taking INH are usually given 25–50 mg of pyridoxine orally daily to help prevent neuropathy.

Lead

Lead is used in a variety of industrial and commercial products, such as storage batteries, solders, paints, pottery, plumbing, and gasoline and is found in some traditional Hispanic and Ayurvedic ethnic medicines.

Lead toxicity usually results from chronic repeated exposure and is rare after a single ingestion. Lead produces a variety of adverse effects on cellular function and primarily affects the nervous system, gastrointestinal tract, and hematopoietic system.

Clinical Findings

Lead poisoning often goes undiagnosed initially because presenting symptoms and signs are nonspecific and exposure is not suspected. Common symptoms include colicky abdominal pain, constipation, headache, and irritability. Severe poisoning may cause coma and convulsions. Chronic intoxication can cause learning disorders (in children) and motor neuropathy (eg, wrist drop). Lead-containing bullet fragments in or near joint spaces can result in chronic lead toxicity.

Diagnosis is based on measurement of the blood lead level. Whole blood lead levels less than 10 mcg/dL are usually considered nontoxic. Levels between 10 and 25 mcg/dL have been associated with impaired neurobehavioral development in children. Levels of 25–50 mcg/dL may be associated with headache, irritability, and subclinical neuropathy. Levels of 50–70 mcg/dL are associated with moderate toxicity, and levels greater than 70–100 mcg/dL are often associated with severe poisoning. Other laboratory findings of lead poisoning include microcytic anemia with basophilic stippling and elevated free erythrocyte protoporphyrin.

See Related Guideline from *CURRENT Practice Guidelines in Primary Care 2009*

Treatment

Emergency and Supportive Measures

For patients with encephalopathy, maintain a patent airway and treat coma and convulsions as described at the beginning of this chapter.

For recent acute ingestion, if a large lead-containing object (eg, fishing weight) is still visible in the stomach on abdominal radiograph, whole bowel irrigation (See Antidotes & Other Treatment-Whole Bowel Irrigation), endoscopy, or even surgical removal may be necessary to prevent subacute lead poisoning. (The acidic gastric contents may corrode the metal surface, enhancing lead absorption. Once the object passes into the small intestine, the risk of toxicity declines.)

Conduct an investigation into the source of the lead exposure.

Workers with a single lead level greater than 60 mcg/dL (or three successive monthly levels greater than 50 mcg/dL) or construction workers with any single blood lead level greater than 50 mcg/dL must by federal law be removed from the site of exposure. Contact the regional office of the United States Occupational Safety and Health Administration (OSHA) for more information. Several states mandate reporting of cases of confirmed lead poisoning.

Specific Treatment

The indications for chelation depend on the blood lead level and the patient's clinical state. A medical toxicologist or regional poison control center (800-222-1222) should be consulted for advice about selection and use of these antidotes.

Note: It is impermissible under the law to treat asymptomatic workers with elevated blood lead levels in order to keep their levels under 50 mcg/dL rather than remove them from the exposure.

Severe toxicity

Patients with severe intoxication (encephalopathy or levels greater than 70–100 mcg/dL) should receive edetate calcium disodium (ethylenediaminetetraacetic acid, EDTA), 1500 mg/m^2/kg/d (approximately 50 mg/kg/d) in four to six divided doses or as a continuous intravenous infusion. Some clinicians also add dimercaprol (BAL), 4–5 mg/kg intramuscularly every 4 hours for 5 days.

Less severe toxicity

Patients with less severe symptoms and asymptomatic patients with blood lead levels between 55 and 69 mcg/dL may be treated with edetate calcium disodium alone in dosages as above. An oral chelator, succimer (DMSA), is available for use in patients with mild to moderate intoxication. The usual dose is 10 mg/kg orally every 8 hours for 5 days, then every 12 hours for 2 weeks.

LSD & Other Hallucinogens

A variety of substances—ranging from naturally occurring plants and mushrooms to synthetic substances such as phencyclidine (PCP), toluene and other solvents, dextromethorphan, and lysergic acid diethylamide

(LSD)—are abused for their hallucinogenic properties. The mechanism of toxicity and the clinical effects vary for each substance.

Many hallucinogenic plants and mushrooms produce anticholinergic delirium (see Mushrooms), characterized by flushed skin, dry mucous membranes, dilated pupils, tachycardia, and urinary retention. Other plants and mushrooms may contain hallucinogenic indoles such as mescaline and LSD, which typically cause marked visual hallucinations and perceptual distortion, widely dilated pupils, and mild tachycardia. PCP, a dissociative anesthetic agent similar to ketamine, can produce fluctuating delirium and coma, often associated with vertical and horizontal nystagmus. Toluene and other hydrocarbon solvents (butane, trichloroethylene, "chemo," etc) cause euphoria and delirium and may sensitize the myocardium to the effects of catecholamines, leading to fatal dysrhythmias.

Treatment

Emergency and Supportive Measures

Maintain a patent airway and assist respirations if necessary. Treat coma, hyperthermia, and seizures as outlined at the beginning of this chapter. For recent large ingestions, consider giving activated charcoal orally or by gastric tube.

Specific Treatment

Patients with anticholinergic delirium may benefit from a dose of physostigmine, 0.5–1 mg intravenously—not to exceed 1 mg/min (see Atropine & Anticholinergics). Dysphoria, agitation, and psychosis associated with LSD or mescaline intoxication may respond to benzodiazepines (eg, lorazepam, 1–2 mg orally or intravenously) or haloperidol (2–5 mg intramuscularly or intravenously). Monitor patients who have sniffed solvents for cardiac dysrhythmias (most commonly premature ventricular contractions, ventricular tachycardia, ventricular fibrillation); treatment with -blockers such as propranolol (1–5 mg intravenously) or esmolol (250–500 mcg/kg intravenously, then 50 mcg/kg/min by infusion) may be more effective than lidocaine.

Jamison SC et al. A 60-year-old woman with agitation and psychosis following ingestion of dextromethorphan and opioid analgesics. J Psychopharmacol. 2008 Jun 26 [Epub ahead of print]. [PMID: 18583439]

Vural M et al. Dilated cardiomyopathy associated with toluene abuse. Cardiology. 2006;105(3):158–61. [PMID: 16479101]

Mercury

Acute mercury poisoning usually occurs by ingestion of inorganic mercuric salts or inhalation of metallic mercury vapor. Ingestion of the mercuric salts causes a burning sensation in the throat, discoloration and edema of oral mucous membranes, abdominal pain, vomiting, bloody diarrhea, and shock. Direct nephrotoxicity causes acute kidney injury. Inhalation of high concentrations of metallic mercury vapor may cause acute fulminant chemical pneumonia. Chronic mercury poisoning causes weakness, ataxia, intention tremors, irritability, and depression. Exposure to alkyl (organic) mercury derivatives from contaminated fish or fungicides used on seeds has caused ataxia, tremors, convulsions, and catastrophic birth defects.

Treatment

Acute Poisoning

There is no effective specific treatment for mercury vapor pneumonitis. Remove ingested mercuric salts by lavage, and administer activated charcoal (see Antidotes & Other Treatment-Activated Charcoal). For acute ingestion of mercuric salts, give dimercaprol (BAL) at once, as for arsenic poisoning. Unless the patient has severe gastroenteritis, consider succimer (DMSA), 10 mg/kg orally every 8 hours for 5 days and then every 12 hours for 2 weeks. Maintain urinary output. Unithiol is a chelator that can be given orally or parenterally, but is not commonly available in the United States. Treat oliguria and anuria if they occur.

Chronic Poisoning

Remove from exposure. Neurologic toxicity is not considered reversible with chelation, though some authors recommend a trial of succimer or uniothiol (contact a regional poison center or medical toxicologist for advice).

Mozaffarian D et al. Fish intake, contaminants, and human health: evaluating the risks and the benefits. JAMA. 2006 Oct 18;296(15):1885–99. [PMID: 17047219]

Needleman HL. Mercury in dental amalgam—a neurotoxic risk? JAMA. 2006 Apr 19;295(15):1835–6. [PMID: 16622146]

Methanol & Ethylene Glycol

Methanol (wood alcohol) is commonly found in a variety of products, including solvents, duplicating fluids, record cleaning solutions, and paint removers. It is sometimes ingested intentionally by alcoholic patients as a substitute for ethanol and may also be found as a contaminant in bootleg whiskey. Ethylene glycol is the major constituent in most antifreeze compounds. The toxicity of both agents is caused by metabolism to highly toxic organic acids—methanol to formic acid; ethylene glycol to glycolic and oxalic acids.

Clinical Findings

Shortly after ingestion of either of these agents, patients usually appear "drunk." The serum osmolality (measured with the freezing point device) is usually increased, but acidosis is often absent early. After several hours, metabolism to toxic organic acids leads to a severe anion gap metabolic acidosis, tachypnea, confusion, convulsions, and coma. Methanol intoxication frequently causes visual disturbances, while ethylene glycol often produces oxalate crystalluria and advanced chronic kidney disease.

Treatment

Emergency and Supportive Measures

For patients presenting within 30–60 minutes after ingestion, empty the stomach by gastric lavage (see Antidotes & Other Treatment-Gastric Lavage). Charcoal is not very effective but should be administered if other poisons or drugs have also been ingested.

Specific Treatment

Patients with significant toxicity (manifested by severe metabolic acidosis, altered mental status, and markedly elevated osmol gap) should undergo hemodialysis as soon as possible to remove the parent compound and the toxic metabolites. Treatment with folic acid, thiamine, and pyridoxine may enhance the breakdown of toxic metabolites.

Ethanol blocks metabolism of the parent compounds by competing for the enzyme alcohol dehydrogenase. Fomepizole (4-methylpyrazole; Antizol) blocks alcohol dehydrogenase and is easier to use than ethanol. A regional poison control center (800-222-1222) should be contacted for indications and dosing.

Methemoglobinemia-Inducing Agents

A large number of chemical agents are capable of oxidizing ferrous hemoglobin to its ferric state (methemoglobin), a form that cannot carry oxygen. Drugs and chemicals known to cause methemoglobinemia include benzocaine (a local anesthetic found in some topical anesthetic sprays and a variety of nonprescription products), aniline, propanil, nitrites, nitrogen oxide gases, nitrobenzene, dapsone, phenazopyridine (Pyridium), and many others. Dapsone has a long elimination half-life and may produce prolonged or recurrent methemoglobinemia.

Clinical Findings

Methemoglobinemia reduces oxygen-carrying capacity and may cause dizziness, nausea, headache, dyspnea, confusion, seizures, and coma. The severity of symptoms depends on the percentage of hemoglobin oxidized to methemoglobin; severe poisoning is usually present when methemoglobin fractions are greater than 40–50%. Even at low levels (15–20%), victims appear cyanotic because of the "chocolate brown" color of methemoglobin, but they have normal PO_2 results on arterial blood gas determinations. Pulse oximetry gives inaccurate oxygen saturation measurements; the reading is often between 85% and 90%. Severe metabolic acidosis may be present. Hemolysis may occur, especially in patients susceptible to oxidant stress (ie, those with glucose-6-phosphate dehydrogenase deficiency).

Treatment

Emergency and Supportive Measures

Administer high-flow oxygen. If the causative agent was recently ingested, administer activated charcoal (see Antidotes & Other Treatment-Activated Charcoal). Repeat-dose activated charcoal may enhance dapsone elimination (see Antidotes and Other Treatments: Increased Drug Removal: Repeat-Dose Charcoal).

Specific Treatment

Methylene blue enhances the conversion of methemoglobin to hemoglobin by increasing the activity of the enzyme methemoglobin reductase. For symptomatic patients, administer 1–2 mg/kg (0.1–0.2 mL/kg of 1% solution) intravenously. The dose may be repeated once in 15–20 minutes if necessary. Patients with hereditary methemoglobin reductase deficiency or glucose-6-phosphate dehydrogenase deficiency may not respond to methylene blue treatment.

Monoamine Oxidase Inhibitors

Overdoses of MAO inhibitors (isocarboxazid, phenelzine, selegiline, moclobemide) cause ataxia, excitement, hypertension, and tachycardia, followed several hours later by hypotension, convulsions, and hyperthermia.

Ingestion of tyramine-containing foods may cause a severe hypertensive reaction in patients taking MAO inhibitors. Foods containing tyramine include aged cheese and red wines. Hypertensive reactions may also occur with any sympathomimetic drug. Severe or fatal hyperthermia (serotonin syndrome) may occur if patients receiving MAO inhibitors are given meperidine, fluoxetine, paroxetine, fluvoxamine, venlafaxine, tryptophan, dextromethorphan, tramadol, or other serotonin-enhancing drugs. This reaction can also occur with the newer selective MAO inhibitor moclobemide, and the antibiotic linezolid, which has MAO-inhibiting properties. The serotonin syndrome has also been reported in patients taking selective serotonin reuptake inhibitors (SSRIs) in large doses or in combination with other SSRIs, even in the absence of an MAO inhibitor or meperidine.

Treatment

Administer activated charcoal (see Antidotes & Other Treatment-Activated Charcoal). Treat severe hypertension with nitroprusside, phentolamine, or other rapid-acting vasodilators (see The Symptomatic Patient: Hypertension). Treat hypotension with fluids and positioning, but avoid use of pressor agents if possible. Observe patients for at least 24 hours, since hyperthermic reactions may be delayed. Treat hyperthermia with aggressive cooling; neuromuscular paralysis may be required (see The Symptomatic Patient: Hyperthermia). Cyproheptadine, 4 mg orally (or by gastric tube) every hour for three or four doses, has been reported to be effective against serotonin syndrome.

Sun-Edelstein C et al. Drug-induced serotonin syndrome. Expert Opin Drug Saf. 2008 Sep;7(5):587–96. [PMID: 18759711]

Mushrooms

There are thousands of mushroom species that cause a variety of toxic effects. The most dangerous species of mushrooms are *Amanita phalloides, Amanita verna, Amanita virosa, Gyromitra esculenta*, and the *Galerina* species, all of which contain amatoxin, a potent cytotoxin. Ingestion of even a portion of one mushroom of a dangerous species may be sufficient to cause death.

The characteristic pathologic finding in fatalities from amatoxin-containing mushroom poisoning is acute massive necrosis of the liver.

Clinical Findings

See Table 38–8.

Table 38–8. Poisonous mushrooms.

Toxin	**Genus**	**Symptoms and Signs**	**Onset**	**Treatment**
Amanitin	*Amanita (A phalloides, A verna, A virosa)*	Severe gastroenteritis followed by delayed hepatic failure and acute kidney injury after 48–72 hours	6–24 hours	Supportive. Correct dehydration. Give repeated doses of activated charcoal orally. Consider silymarin (silibinin) (see text).
Muscarine	*Inocybe*,	Muscarinic	30–	Supportive

	Clitocybe	(salivation, miosis, bradycardia, diarrhea)	60 minutes	. Give atropine, 0.5–2 mg intravenously, for severe cholinergic symptoms and signs.
Ibotenic acid, muscimol	*Amanita muscaria* ("fly agaric")	Anticholinergic (mydriasis, tachycardia, hyperpyrexia, delirium)	30–60 minutes	Supportive. Give physostigmine, 0.5–2 mg intravenously, for severe anticholinergic symptoms and signs.
Coprine	*Coprinus*	Disulfiram-like effect occurs with ingestion of ethanol	30–60 minutes	Supportive. Abstain from ethanol for 3–4 days.
Monomethylhyd	*Gyromit*	Gastroenter	6–12	Supportive

razine	*ra*	itis; occasionally hemolysis, hepatic failure, and acute kidney injury	hours	. Correct dehydration. Pyridoxine, 2.5 mg/kg intravenously, may be helpful.
Orellanine	*Cortinarius*	Nausea, vomiting; acute kidney injury after 1–3 weeks	2–14 days	Supportive.
Psilocybin	*Psilocybe*	Hallucinations	15–30 minutes	Supportive.
Gastrointestinal irritants	Many species	Nausea and vomiting, diarrhea	$^{1}/2$–2 hours	Supportive. Correct dehydration.

Symptoms and Signs

Amatoxin-type cyclopeptides

(*A phalloides*, *A verna*, *A virosa*, and *Galerina* species.) After a latent interval of 8–12 hours, severe abdominal cramps and vomiting begin and progress to profuse diarrhea, followed in 1–2 days by hepatic necrosis, hepatic encephalopathy, and frequently acute kidney injury. The fatality rate is about 20%. Cooking the mushrooms does not prevent poisoning.

Gyromitrin type

(*Gyromitra* and *Helvella* species.) Toxicity is more common following ingestion of uncooked mushrooms. Vomiting, diarrhea, hepatic necrosis, convulsions, coma, and hemolysis may occur after a latent period of 8–12 hours. The fatality rate is probably less than 10%.

Muscarinic type

(*Inocybe* and *Clitocybe* species.) Vomiting, diarrhea, bradycardia, hypotension, salivation, miosis, bronchospasm, and lacrimation occur shortly after ingestion. Cardiac arrhythmias may occur. Fatalities are rare.

Anticholinergic type

(Eg, *Amanita muscaria*, *Amanita pantherina*.) This type causes a variety of symptoms that may be atropine-like, including excitement, delirium, flushed skin, dilated pupils, and muscular jerking tremors, beginning 1–2 hours after ingestion. Fatalities are rare.

Gastrointestinal irritant type

(Eg, *Boletus*, *Cantharellus*.) Nausea, vomiting, and diarrhea occur shortly after ingestion. Fatalities are rare.

Disulfiram type

(*Coprinus* species.) Disulfiram-like sensitivity to alcohol may persist for several days. Toxicity is characterized by flushing, hypotension, and vomiting after coingestion of alcohol.

Hallucinogenic

(*Psilocybe* and *Panaeolus* species.) Mydriasis, nausea and vomiting, and intense visual hallucinations occur 1–2 hours after ingestion. Fatalities are rare.

Cortinarius orellanus

This mushroom may cause acute kidney injury due to tubulointerstitial nephritis. *Amanita smithiana* has also been reported to cause acute kidney injury.

Treatment

Emergency Measures

After the onset of symptoms, efforts to remove the toxic agent are probably useless, especially in cases of amatoxin or gyromitrin poisoning, where there is usually a delay of 12 hours or more before symptoms occur and patients seek medical attention. However, induction of vomiting or administration of activated charcoal is recommended for any recent ingestion of an unidentified or potentially toxic mushroom (see Antidotes & Other Treatment-Activated Charcoal).

General Measures

Amatoxin-type cyclopeptides

A variety of antidotes (eg, thioctic acid, penicillin, corticosteroids) have been suggested for amatoxin-type mushroom poisoning, but controlled studies are lacking and experimental data in animals are equivocal. Aggressive fluid replacement for diarrhea and intensive supportive care for hepatic failure are the mainstays of treatment. Silymarin (silibinin), a derivative of milk thistle, is commonly used in Europe but is not available in the United States as a pharmaceutical grade intravenous preparation.

Interruption of enterohepatic circulation of the amatoxin by the administration of activated charcoal or by cannulation and drainage of the bile duct may be of value.

Liver transplant may be the only hope for survival in gravely ill patients—contact a liver transplant center early.

Gyromitrin type

For gyromitrin poisoning, give pyridoxine, 25 mg/kg intravenously.

Muscarinic type

For mushrooms producing predominantly muscarinic-cholinergic symptoms, give atropine, 0.005–0.01 mg/kg intravenously, and repeat as needed.

Anticholinergic type

For anticholinergic type, physostigmine, 0.5–1 mg intravenously, may calm extremely agitated patients and reverse peripheral anticholinergic manifestations, but it may also cause bradycardia, asystole, and seizures. Alternately, use a benzodiazepine such as lorazepam, 1–2 mg intravenously.

Gastrointestinal irritant type

Treat with antiemetics and intravenous or oral fluids.

Disulfiram type

For *Coprinus* ingestion, avoid alcohol. Treat alcohol reaction with fluids and supine position.

Hallucinogenic type

Provide a quiet, supportive atmosphere. Diazepam or haloperidol may be used for sedation.

Cortinarius

Provide supportive care and hemodialysis as needed for acute kidney injury.

Yang WS et al. Acute renal failure caused by mushroom poisoning. J Formos Med Assoc. 2006 Mar;105(3):263–7. [PMID: 16520846]

Opioids

Prescription and illicit opioids (morphine, heroin, codeine, oxycodone, fentanyl, hydromorphone, etc) are popular drugs of abuse and the cause of frequent hospitalizations for overdose. These drugs have widely varying potencies and durations of action; for example, some of the illicit fentanyl derivatives are up to 2000 times more potent than morphine. All of these agents decrease central nervous system activity and sympathetic outflow by acting on opiate receptors in the brain. Tramadol is an analgesic that is unrelated chemically to the opioids but acts on opioid receptors. Buprenorphine is a partial agonist-antagonist opioid used for the outpatient treatment of opioid addiction.

Clinical Findings

Mild intoxication is characterized by euphoria, drowsiness, and constricted pupils. More severe intoxication may cause hypotension, bradycardia, hypothermia, coma, and respiratory arrest. Pulmonary edema may occur. Death is usually due to apnea or pulmonary aspiration of gastric contents. Propoxyphene may cause seizures and prolongation of the QRS interval. Methadone has been associated with QT interval prolongation and torsades de pointes. Tramadol, dextromethorphan, and meperidine also occasionally cause seizures. With meperidine, the metabolite normeperidine is probably the cause of seizures and is most likely to accumulate with repeated dosing in patients with chronic kidney disease. While the duration of effect for heroin is usually 3–5 hours, methadone intoxication may last for 48–72 hours or longer. Many opioids, including fentanyl, tramadol, oxycodone, and methadone, are not detected on routine urine toxicology "opiate" screening. Wound botulism has been associated with skin-popping, especially involving "black tar" heroin. Buprenorphine added to an opioid regimen may produce acute narcotic withdrawal symptoms.

Treatment

Emergency and Supportive Measures

Protect the airway and assist ventilation. Administer activated charcoal (see Antidotes & Other Treatment-Activated Charcoal).

Specific Treatment

Naloxone is a specific opioid antagonist that can rapidly reverse signs of narcotic intoxication. Although it is structurally related to the opioids, it has no agonist effects of its own. Administer 0.4–2 mg intravenously, and repeat as needed to awaken the patient and maintain airway protective reflexes and spontaneous breathing. Very large doses (10–20 mg) may be required for patients intoxicated by some opioids (eg, propoxyphene, codeine, fentanyl derivatives). **Caution:** The duration of effect of naloxone is only about 2–3 hours; repeated doses may be necessary for patients intoxicated by long-acting drugs such as methadone. Continuous observation for at least 3 hours after the last naloxone dose is mandatory.

Paraquat

Paraquat is used as a herbicide. Concentrated solutions of paraquat are highly corrosive to the oropharynx, esophagus, and stomach. The fatal dose after absorption may be as small as 4 mg/kg. If ingestion of paraquat is not rapidly fatal because of its corrosive effects, the herbicide may cause progressive pulmonary fibrosis, with death ensuing after 2–3 weeks. Patients with plasma paraquat levels above 2 mg/L at 6 hours or 0.2 mg/L at 24 hours are likely to die.

Treatment

Remove ingested paraquat by immediate induced emesis, or by gastric lavage if the patient is already in a health care facility (see Antidotes & Other Treatment-Gastric Lavage). Clay (bentonite or fuller's earth) and activated charcoal are effective adsorbents. Administer repeated doses of 60 g of activated charcoal by gastric tube every 2 hours for at least three or four doses. Charcoal hemoperfusion, 8 hours per day for 2–3 weeks, has been anecdotally reported to be lifesaving, but clinical and animal studies are equivocal. Supplemental oxygen should be withheld unless the PaO_2 is less than 70 mm Hg because oxygen may contribute to the pulmonary damage, which is mediated through lipid peroxidation. Immunosuppressive therapy (cyclophosphamide with dexamethasone) has shown possible benefit in anecdotal reports.

Pesticides: Cholinesterase Inhibitors

Organophosphorus and carbamate insecticides (organophosphates: parathion, malathion, etc; carbamates: carbaryl, aldicarb, etc) are widely used in commercial agriculture and home gardening and have largely replaced older, more environmentally persistent organochlorine compounds such as DDT and chlordane. The organophosphates and carbamates—also called anticholinesterases because they inhibit the enzyme acetylcholinesterase—cause an increase in acetylcholine activity at nicotinic and muscarinic receptors and in the central nervous system. There are a variety of chemical agents in this group, with widely varying potencies. Most of them are poorly water-soluble, are formulated with an aromatic hydrocarbon solvent such as xylene, and are well absorbed through intact skin. Most chemical warfare "nerve agents" (see above) are organophosphates.

Clinical Findings

Inhibition of cholinesterase results in abdominal cramps, diarrhea, vomiting, excessive salivation, sweating, lacrimation, miosis (constricted pupils), wheezing and bronchorrhea, seizures, and skeletal muscle weakness. Initial tachycardia is usually followed by bradycardia. Profound skeletal muscle weakness, aggravated by excessive bronchial secretions and wheezing, may result in respiratory arrest and death. Symptoms and signs of poisoning may persist or recur over several days, especially with highly lipid-soluble agents such as fenthion or dimethoate.

The diagnosis should be suspected in patients who present with miosis, sweating, and hyperperistalsis. Serum and red blood cell cholinesterase activity is usually depressed at least 50% below baseline in those victims who have severe intoxication.

Treatment

Emergency and Supportive Measures

If the agent was recently ingested, empty the stomach by gastric lavage and administer activated charcoal (see Antidotes & Other Treatment-Activated Charcoal). If the agent is on the victim's skin or hair, wash repeatedly with soap or shampoo and water. Providers must take care to avoid skin exposure by wearing gloves and waterproof aprons. Dilute hypochlorite solution (eg, household bleach diluted 1:10) is reported to help break down organophosphate pesticides and nerve agents on equipment or clothing.

Specific Treatment

Atropine reverses excessive muscarinic stimulation and is effective for treatment of salivation, bronchial hypersecretion, wheezing, abdominal cramping, and sweating. However, it does not interact with nicotinic receptors at autonomic ganglia and at the neuromuscular junction and has no effect on muscle weakness. Administer 2 mg intravenously, and if there is no response after 5 minutes, give repeated boluses in rapidly escalating doses as needed to dry bronchial secretions and decrease wheezing; as much as several hundred milligrams of atropine has been given to treat severe poisoning.

Pralidoxime (2-PAM, Protopam) is a specific antidote that reverses organophosphate binding to the cholinesterase enzyme; therefore, it is effective at the neuromuscular junction as well as other nicotinic and muscarinic sites. It is most likely to be effective if started very soon after poisoning, to prevent permanent binding of the organophosphate to cholinesterase. Clinical studies are conflicting regarding the effectiveness of pralidoxime in reducing mortality. It appears to be more effective for chlorpyrifos compared with dimethoate poisoning. Administer 1–2 g intravenously as a loading dose, and begin a continuous infusion (200–500 mg/h, titrated to clinical response). Continue to give pralidoxime as long as there is any evidence of acetylcholine excess. Pralidoxime is of questionable benefit for carbamate poisoning, because carbamates have only a transitory effect on the cholinesterase enzyme. High-dose sodium bicarbonate (5 mEq/kg intravenously over 5 minutes) has been reported effective although the mechanism is unclear and the treatment has not been widely adopted.

Petroleum Distillates & Solvents

Petroleum distillate toxicity may occur from inhalation of the vapor or as a result of pulmonary aspiration of the liquid during or after ingestion. Acute manifestations of aspiration pneumonitis are vomiting, coughing, and bronchopneumonia. Some hydrocarbons—ie, those with aromatic or halogenated subunits—can also cause severe systemic poisoning after oral ingestion. Hydrocarbons can also cause systemic intoxication by inhalation. Vertigo, muscular incoordination, irregular pulse, myoclonus, and seizures occur with serious poisoning and may be due to hypoxemia or the systemic effects of the agents. Chlorinated and fluorinated hydrocarbons (trichloroethylene, Freons, etc) and many other hydrocarbons can cause ventricular arrhythmias due to increased sensitivity of the myocardium to the effects of endogenous catecholamines.

Treatment

Remove the patient to fresh air. For simple aliphatic hydrocarbon ingestion, gastric emptying and activated charcoal are not recommended, but these procedures may be indicated if the preparation contains toxic solutes (eg, an insecticide) or is an aromatic or halogenated product. Observe the victim for 6–8 hours for signs of aspiration pneumonitis (cough, localized rales or rhonchi, tachypnea, and infiltrates on chest radiograph). Corticosteroids are not recommended. If fever occurs, give a specific antibiotic only after identification of bacterial pathogens by laboratory studies. Because of the risk of arrhythmias, use bronchodilators with caution in patients with chlorinated or fluorinated solvent intoxication. If tachyarrhythmias occur, use esmolol intravenously 25–100 mcg/kg/min.

Phenothiazines & Other Antipsychotic Agents

Promethazine, prochlorperazine, chlorpromazine, haloperidol, droperidol, risperidone, olanzapine, ziprasidone, quetiapine, and aripiprazole are used as antiemetics and antipsychotic agents and as potentiators of analgesic and hypnotic drugs.

Phenothiazines (particularly chlorpromazine) induce drowsiness and mild orthostatic hypotension in as many as 50% of patients. Larger doses can cause obtundation, miosis, severe hypotension, tachycardia, convulsions, and coma. Abnormal cardiac conduction may occur, resulting in prolongation of QRS or QT intervals (or both) and ventricular arrhythmias. (Droperidol now has a "black box" warning about prolonged QT interval and the risk of torsades de pointes.) Among the newer agents, quetiapine is more likely to cause coma and hypotension.

With therapeutic or toxic doses, an acute extrapyramidal dystonic reaction may develop in some patients, with spasmodic contractions of the face and neck muscles, extensor rigidity of the back muscles, carpopedal spasm, and motor restlessness. This reaction is more common with haloperidol and the butyrophenones and less common with newer atypical antipsychotics such as ziprasidone, olanzapine, aripiprazole, and quetiapine. Severe rigidity accompanied by hyperthermia and metabolic acidosis ("neuroleptic malignant syndrome") may occasionally occur and is life-threatening (see Chapter 25: Psychiatric Disorders).

Treatment

Emergency and Supportive Measures

Administer activated charcoal. For severe hypotension, treatment with intravenous fluids and pressor agents may be necessary. Treat hyperthermia as outlined in The Symptomatic Patient: Hyperthermia. Maintain cardiac monitoring.

Specific Treatment

Hypotension and cardiac arrhythmias associated with widened QRS intervals on the ECG in a patient with thioridazine poisoning may respond to intravenous sodium bicarbonate as used for tricyclic antidepressants. Prolongation of the QT interval and torsades de pointes is usually treated with intravenous magnesium or overdrive pacing (see Arrhythmias: Treatment).

For extrapyramidal signs, give diphenhydramine, 0.5–1 mg/kg intravenously, or benztropine mesylate, 0.01–0.02 mg/kg intramuscularly. Treatment with oral doses of these agents should be continued for 24–48 hours.

Bromocriptine (2.5–7.5 mg orally daily) may be effective for mild or moderate neuroleptic malignant syndrome. Dantrolene (2–5 mg/kg intravenously) has also been used for muscle contractions but is not a true antidote.

Quinidine & Related Antiarrhythmics

Quinidine, procainamide, and disopyramide are class Ia antiarrhythmic agents, and flecainide and propafenone are class Ic agents. These drugs have membrane-depressant effects on the sodium-dependent channel responsible for cardiac cell depolarization. Manifestations of cardiotoxicity include arrhythmias, syncope, hypotension, and widening of the QRS complex on the ECG (> 100–120 ms). With type Ia drugs, a lengthened QT interval and atypical or polymorphous ventricular tachycardia (torsades de pointes) may occur. The antimalarials chloroquine and hydroxychloroquine have similar effects in overdose.

Treatment

Emergency and Supportive Measures

Administer activated charcoal (see Antidotes & Other Treatment-Activated Charcoal); consider gastric lavage after large recent overdose. Assist ventilation if needed. Perform continuous cardiac monitoring.

Specific Treatment

Treat cardiotoxicity (hypotension, QRS interval widening) with intravenous boluses of sodium bicarbonate, 50–100 mEq. Torsades de pointes may be treated with intravenous magnesium or overdrive pacing.

Salicylates

Salicylates (aspirin, methyl salicylate, etc) are found in a variety of over-the-counter and prescription medications. Salicylates uncouple cellular oxidative phosphorylation, resulting in anaerobic metabolism and excessive production of lactic acid and heat, and they also interfere with several Krebs cycle enzymes. A single ingestion of more than 200 mg/kg of salicylate is likely to produce significant acute intoxication. Poisoning may also occur as a result of chronic excessive dosing over several days. Although the half-life of salicylate is 2–3 hours after small doses, it may increase to 20 hours or more in patients with intoxication.

Clinical Findings

Acute ingestion often causes nausea and vomiting, occasionally with gastritis. Moderate intoxication is characterized by hyperpnea (deep and rapid breathing), tachycardia, tinnitus, and elevated anion gap metabolic acidosis. Serious intoxication may result in agitation, confusion, coma, seizures, cardiovascular collapse, pulmonary edema, hyperthermia, and death. The prothrombin time is often elevated owing to salicylate-induced hypoprothrombinemia.

Diagnosis is suspected in any patient with metabolic acidosis and is confirmed by measuring the serum salicylate level. Patients with levels greater than 100 mg/dL (1000 mg/L) after an acute overdose are more likely to have severe poisoning. On the other hand, patients with subacute or chronic intoxication may suffer severe symptoms with levels of only 60–70 mg/dL. The arterial blood gas typically reveals a respiratory alkalosis with an underlying metabolic acidosis.

Treatment

Emergency and Supportive Measures

Administer activated charcoal (see Antidotes & Other Treatment-Activated Charcoal). Gastric lavage followed by administration of extra doses of activated charcoal may be needed in patients who ingest more than 10 g of aspirin (see Antidotes & Other Treatment-Activated Charcoal). The desired ratio of charcoal to aspirin is about 10:1 by weight; while this cannot always be given as a single dose, it may be administered over the first 24 hours in divided doses every 2–4 hours. Treat metabolic acidosis with intravenous sodium bicarbonate. This is critical because acidosis (especially acidemia, pH < 7.40) promotes greater entry of salicylate into cells, worsening toxicity. Brief hypoventilation during rapid sequence intubation may cause sudden and severe deterioration if the pH is allowed to fall.

Specific Treatment

Alkalinization of the urine enhances renal salicylate excretion by trapping the salicylate anion in the urine. Add 100 mEq (two ampules) of sodium bicarbonate to 1 L of 5% dextrose in 0.2% saline, and infuse this solution intravenously at a rate of about 150–200 mL/h. Unless the patient is oliguric or hyperkalemic, add 20–30 mEq of potassium chloride to each liter of intravenous fluid. Patients who are volume-depleted often fail to produce an alkaline urine (paradoxical aciduria) unless potassium is given.

Hemodialysis may be lifesaving and is indicated for patients with severe metabolic acidosis, markedly altered mental status, or significantly elevated salicylate levels (eg, > 100–120 mg/dL [1000–1200 mg/L] after acute overdose or > 60–70 mg/dL [600–700 mg/L] with subacute or chronic intoxication).

Seafood Poisonings

A variety of intoxications may occur after eating certain types of fish or other seafood. These include scombroid, ciguatera, paralytic shellfish, and puffer fish poisoning. The mechanisms of toxicity and clinical presentations are described in Table 38–9. In the majority of cases, the seafood has a normal appearance and taste (scombroid may have a peppery taste).

Table 38–9. Common seafood poisonings.

Type of Poisoning	**Mechanism**	**Clinical Presentation**
Ciguatera	Reef fish ingest toxic dinoflagellates, whose toxins accumulate in fish	1–6 hours after ingestion, victims develop abdominal pain, vomiting, and

	meat. Commonly implicated fish in the United States are barracuda, jack, snapper, and grouper.	diarrhea accompanied by a variety of neurologic symptoms, including paresthesias, reversal of hot and cold sensation, vertigo, headache, and intense itching. Autonomic disturbances, including hypotension and bradycardia, may occur.
Scombroid	Improper preservation of large fish results in bacterial degradation of histidine to histamine. Commonly implicated fish include tuna, mahimahi, bonita, mackerel, and kingfish.	Allergic-like (anaphylactoid) symptoms are due to histamine, usually begin within 15–90 minutes, and include skin flushing, itching, urticaria, angioedema, bronchospasm, and hypotension as well as abdominal pain, vomiting, and diarrhea.
Paralytic	Dinoflagellates	Onset is usually

shellfish poisoning	produce saxitoxin, which is concentrated by filter-feeding mussels and clams. Saxitoxin blocks sodium conductance and neuronal transmission in skeletal muscles.	within 30–60 minutes. Initial symptoms include perioral and intraoral paresthesias. Other symptoms include nausea and vomiting, headache, dizziness, dysphagia, dysarthria, ataxia, and rapidly progressive muscle weakness that may result in respiratory arrest.
Puffer fish poisoning	Tetrodotoxin is concentrated in liver, gonads, intestine, and skin. Toxic effects are similar to those of saxitoxin. Tetrodotoxin is also found in some North American newts and Central American frogs.	Onset is usually within 30–40 minutes but may be as short as 10 minutes. Initial perioral paresthesias are followed by headache, diaphoresis, nausea, vomiting, ataxia, and rapidly progressive muscle weakness that may result in respiratory arrest.

Treatment

Emergency and Supportive Measures

Caution: Abrupt respiratory arrest may occur in patients with acute paralytic shellfish and puffer fish poisoning. Observe patients for at least 4–6 hours. Replace fluid and electrolyte losses from gastroenteritis with intravenous saline or other crystalloid solution.

For recent ingestions, it may be possible to adsorb residual toxin in the gut with activated charcoal, 50–60 g orally (see Antidotes & Other Treatment-Activated Charcoal).

Specific Treatment

There is no specific antidote for paralytic shellfish or puffer fish poisoning.

Ciguatera

There are anecdotal reports of successful treatment of acute neurologic symptoms with mannitol, 1 g/kg intravenously, but this approach is not widely accepted.

Scombroid

Antihistamines such as diphenhydramine, 25–50 mg intravenously, and the H_2 blocker cimetidine, 300 mg intravenously, are usually effective. For severe reactions, give also epinephrine, 0.3–0.5 mL of a 1:1000 solution subcutaneously.

Wang DZ. Neurotoxins from marine dinoflagellates: a brief review. Mar Drugs. 2008 Jun 11;6(2):349–71. [PMID: 18728731]

Snake Bites

The venom of poisonous snakes and lizards may be predominantly neurotoxic (coral snake) or predominantly cytolytic (rattlesnakes, other pit vipers). Neurotoxins cause respiratory paralysis; cytolytic venoms cause tissue destruction by digestion and hemorrhage due to hemolysis and destruction of the endothelial lining of the blood vessels. The manifestations of rattlesnake envenomation are mostly local pain, redness, swelling, and extravasation of blood. Perioral tingling, metallic taste, nausea and vomiting, hypotension, and coagulopathy may also occur. Neurotoxic envenomation may cause ptosis, dysphagia, diplopia, and respiratory arrest.

Treatment

Emergency Measures

Immobilize the patient and the bitten part in a neutral position. Avoid manipulation of the bitten area. Transport the patient to a medical facility for definitive treatment. Do *not* give alcoholic beverages or stimulants; do *not* apply ice; do *not* apply a tourniquet. The trauma to underlying structures resulting from incision and suction performed by unskilled people is probably not justified in view of the small amount of venom that can be recovered.

Specific Antidote and General Measures

Pit viper (eg, rattlesnake) envenomation

For local signs such as swelling, pain, and ecchymosis but no systemic symptoms, give 4–6 vials of crotalid antivenin (CroFab) by slow intravenous drip in 250–500 mL saline. Repeated doses of 2 vials every 6 hours for up to 18 hours has been recommended. For more serious envenomation with marked local effects and systemic toxicity (eg, hypotension, coagulopathy), higher doses and additional vials may be required. Monitor vital signs and the blood coagulation profile. Type and cross-match blood. The adequacy of venom neutralization is indicated by improvement in symptoms and signs, and the rate that swelling slows. Prophylactic antibiotics are not indicated after a rattlesnake bite.

Elapid (coral snake) envenomation

Give 1–2 vials of specific antivenom as soon as possible. To locate antisera for exotic snakes, call a regional poison control center (800-222-1222).

Spider Bites & Scorpion Stings

The toxin of most species of spiders in the United States causes only local pain, redness, and swelling. That of the more venomous black widow spiders *(Latrodectus mactans)* causes generalized muscular pains, muscle spasms, and rigidity. The brown recluse spider *(Loxosceles reclusa)* causes progressive local necrosis as well as hemolytic reactions (rare). Stings by most scorpions in the United States cause only local pain.

Stings by the more toxic *Centruroides* species (found in the southwestern United States) may cause muscle cramps, twitching and jerking, and occasionally hypertension, convulsions, and pulmonary edema. Stings by scorpions from other parts of the world are not discussed here.

Treatment

Black Widow Spider Bites

Pain may be relieved with parenteral narcotics or muscle relaxants (eg, methocarbamol, 15 mg/kg). Calcium gluconate 10%, 0.1–0.2 mL/kg intravenously, may relieve muscle rigidity, though its effectiveness is questionable. Antivenin is available, but because of concerns about acute hypersensitivity reactions (horse serum-derived), it is often reserved for very young or elderly patients or those who do not respond to the above measures. Horse serum sensitivity testing is required. (Instruction and testing materials are included in the antivenin kit.)

Brown Recluse Spider Bites

Because bites occasionally progress to extensive local necrosis, some authorities recommend early excision of the bite site, whereas others use oral corticosteroids. Anecdotal reports have claimed success with dapsone and colchicine. All of these treatments remain of unproved value.

Scorpion Stings

No specific treatment is available for envenomations by scorpions found in the United States. For *Centruroides* stings, some toxicologists use a specific antivenom developed in Arizona, but this is neither FDA-approved nor widely available.

Theophylline & Caffeine

Theophylline may cause intoxication after an acute single overdose, or intoxication may occur as a result of chronic accidental repeated overmedication or reduced elimination resulting from hepatic dysfunction or interacting drug (eg, cimetidine, erythromycin). The usual serum half-life of theophylline is 4–6 hours, but this may increase to more than 20 hours after overdose. Caffeine and caffeine-containing herbal products can produce similar toxicity.

Clinical Findings

Mild intoxication causes nausea, vomiting, tachycardia, and tremulousness. Severe intoxication is characterized by ventricular and supraventricular tachyarrhythmias, hypotension, and seizures. Status epilepticus is common and often intractable to the usual anticonvulsants. After acute overdose (but not chronic intoxication), hypokalemia, hyperglycemia, and metabolic acidosis are common. Seizures and other manifestations of toxicity may be delayed for several hours after acute ingestion, especially if a sustained-release preparation such as Theo-Dur was taken.

Diagnosis is based on measurement of the serum theophylline concentration. Seizures and hypotension are likely to develop in acute overdose patients with serum levels greater than 100 mg/L. Serious toxicity may develop at lower levels (ie, 40–60 mg/L) in patients with chronic intoxication.

Treatment

Emergency and Supportive Measures

After acute ingestion, administer activated charcoal (see Antidotes & Other Treatment-Activated Charcoal). Repeated doses of activated charcoal may enhance theophylline elimination by "gut dialysis." Addition of whole bowel irrigation should be considered for large ingestions involving sustained-release preparations.

Hemodialysis is effective in removing theophylline and is indicated for patients with status epilepticus or markedly elevated serum theophylline levels (eg, > 100 mg/L after acute overdose or > 60 mg/L with chronic intoxication).

Specific Treatment

Treat seizures with benzodiazepines (lorazepam, 2–3 mg intravenously, or diazepam, 5–10 mg intravenously) or phenobarbital (10–15 mg/kg intravenously). Phenytoin is not effective. Hypotension and tachycardia—which are mediated through excessive -adrenergic stimulation—may respond to -blocker therapy even in low doses. Administer esmolol, 25–50 mcg/kg/min by intravenous infusion, or propranolol, 0.5–1 mg intravenously.

Tricyclic & Other Antidepressants

Tricyclic and related cyclic antidepressants are among the most dangerous drugs involved in suicidal overdose. These drugs have anticholinergic and cardiac depressant properties ("quinidine-like" sodium channel blockade). Tricyclic antidepressants produce more marked membrane-depressant cardiotoxic effects than the phenothiazines.

Newer antidepressants such as trazodone, fluoxetine, citalopram, paroxetine, sertraline, bupropion, venlafaxine, and fluvoxamine are not chemically related to the tricyclic antidepressant agents and do not generally produce quinidine-like cardiotoxic effects. However, they may cause seizures in overdoses and they may cause serotonin syndrome (see Monoamine Oxidase Inhibitors, above).

Clinical Findings

Signs of severe intoxication may occur abruptly and without warning within 30–60 minutes after acute tricyclic overdose. Anticholinergic effects include dilated pupils, tachycardia, dry mouth, flushed skin, muscle twitching, and decreased peristalsis. Quinidine-like cardiotoxic effects include QRS interval widening (> 0.12 s; see Figure 38–2: illustration), ventricular arrhythmias, AV block, and hypotension. Rightward-axis deviation of the terminal 40 ms of the QRS has also been described. Prolongation of the QT interval has been reported with citalopram and venlafaxine. Seizures and coma are common with severe intoxication. Life-threatening hyperthermia may result from status epilepticus and anticholinergic-induced impairment of sweating. Among newer agents, bupropion and venlafaxine have been associated with a greater risk of seizures.

Figure 38–2

Cardiac arrhythmias resulting from tricyclic antidepressant overdose. **A:** Delayed intraventricular conduction results in prolonged QRS interval (0.18 s). **B** and **C:** Supraventricular tachycardia with progressive widening of QRS complexes mimics ventricular tachycardia. (Reproduced, with permission, from Benowitz NL, Goldschlager N. Cardiac disturbances in the toxicologic patient. In: Haddad LM, Winchester JF [editors], *Clinical Management of Poisoning and Drug Overdose*, 3rd edition. Saunders/Elsevier, 1998.)

The diagnosis should be suspected in any overdose patient with anticholinergic side effects, especially if there is widening of the QRS interval or seizures. For intoxication by most tricyclic antidepressants, the QRS interval correlates with the severity of intoxication more reliably than the serum drug level.

Serotonin syndrome should be suspected if agitation, delirium, muscular hyperactivity, and fever develop in a patient taking serotonin reuptake inhibitors.

Treatment

Emergency and Supportive Measures

Observe patients for at least 6 hours, and admit all patients with evidence of anticholinergic effects (eg, delirium, dilated pupils, tachycardia) or signs of cardiotoxicity (see above).

Administer activated charcoal, and consider gastric lavage after recent large ingestions (see Antidotes & Other Treatment-Activated Charcoal and -Gastric Lavage). All of these drugs are highly tissue-bound and are not effectively removed by hemodialysis procedures.

Specific Treatment

Cardiotoxic sodium channel-depressant effects of tricyclic antidepressants may respond to boluses of sodium bicarbonate (50–100 mEq intravenously). Sodium bicarbonate provides a large sodium load that alleviates depression of the sodium-dependent channel. Reversal of acidosis may also have beneficial effects at this site. Maintain the pH between 7.45 and 7.50. Alkalinization does not promote excretion of tricyclic antidepressants. Prolongation of the QT interval or torsades de pointes is usually treated with intravenous magnesium or overdrive pacing. Fab antibodies have been developed for some tricyclic antidepressants, but they remain experimental.

Mild serotonin syndrome may be treated with benzodiazepines and withdrawal of the antidepressant. Moderate cases may respond to cyproheptadine (4 mg orally or via gastric tube hourly for three or four doses). Severe hyperthermia should be treated with neuromuscular paralysis and endotracheal intubation in addition to external cooling measures.

Cancer: Introduction

The major features of this chapter are the clinical aspects of cancer, including etiology and prevention; staging; diagnosis and treatment of common cancers; and recognition and management of complications from cancer. Additional information may be obtained from the National Cancer Institute (NCI) website at www.cancer.gov/cancerinformation, the American Society of Clinical Oncology website at www.asco.org, and the National Comprehensive Cancer Network (NCCN) website at www.nccn.org. The NCCN website provides detailed, evidence-based recommendations for management of specific cancers as well as guidelines for cancer screening and for supportive care. General reviews in oncology can be obtained from Medscape Hematology/Oncology (www.medscape.com).

Etiology

Cancer is the second most common cause of death in the United States. In 2008, an estimated 1,437,180 cases of cancer were diagnosed, and 565,650 persons died as a result of cancer. Based on cancer rates determined in 2003–2005, more than 40% of people born today will have cancer diagnosed at some point in their lifetime. Table 39–1 lists the 10 leading cancer types in men and women by site.

Table 39–1. Estimated 10 most common cancer cases in the United States in males and females (all races).

Rank	**Males (745,180 Total Cases)**	**Percent**	**Females (692,000 Total Cases)**	**Percent**

9	Leukemia	3	Kidney and renal pelvis	3
10	Pancreas	3	Leukemia	3
	Other sites	20	Other sites	23

Data from the American Cancer Society, 2008.

However, the incidence of cancer in both men and women is decreasing. In 2008, the American Cancer Society, NCI, and the Centers for Disease Control and Prevention reported that the incidence of all cancers for both sexes decreased 0.8% per year from 1999 through 2005. In men, the rate decreased 1.8% per year from 2001 through 2005, largely because the incidence of the three most common cancers (prostate, lung, colorectum) decreased. In women, the rate decreased 0.6% per year from 1998 through 2005 due to the decline in incidence of two of the top three cancers (breast, colorectum); the incidence of the third cancer (lung) was steady.

Over the last two decades, the decreasing incidence of cancer has translated into a decrease in cancer death rates. Ten of the top 15 cancer sites have shown a decrease in mortality events. Only esophageal cancer in men, pancreatic cancer in women, and hepatocellular in both men and women have increased in mortality numbers. This decline in mortality has been seen in all ethnic and racial groups except for American Indians and Alaskan Natives.

Reductions in cancer incidence and mortality reflect a successful implementation of a broad strategy of prevention, detection, and treatment.

Modifiable Risk Factors

Tobacco is the most common preventable cause of cancer death; it is estimated that at least 30% of all cancer deaths in the United States are directly linked to tobacco. A total of 440,000 cancer deaths in the United States and 4.8 million cancer deaths worldwide can be directly attributed to tobacco abuse. Clear evidence links at least 15 cancers to tobacco use. The most dramatic link is with lung cancer, the most common non-dermatologic malignancy; over 90% of lung cancer cases occur in smokers. Any strategy for cancer control must start with the goal of markedly reducing if not eliminating tobacco use.

Strategies for tobacco control should involve a focus on the individual as well as society as a whole. Tobacco cessation directed toward the individual should start with the clinician providing counseling. Simple, concise advice from a clinician can yield cessation rates of 10–20%. Additive strategies include more intensive counseling; nicotine replacement therapy with patches, gum, or lozenges; and prescription medication with bupropion or varenicline. Perhaps a more intriguing phenomenon, with potential for significant impact on cessation rates, is the influence of social contact behavior on an individual smoker's abstinence decision. For instance, analysis of the Framingham Heart Study demonstrated that smoking cessation by a spouse resulted in a 67% decrease in the subject's likelihood of continuing to smoke, and smoking cessation by a friend resulted in a 36% decrease in the subject's likelihood of smoking.

On a societal level, many initiatives have been put into place to actively discourage tobacco use. State or local laws regulating tobacco use in restaurants, the workplace, and other public places have resulted in declines in tobacco use. Countermarketing with aggressive anti-tobacco advertisements has also contributed to tobacco cessation and abstinence. The key recipients of these messages are children; 80% of smokers will start by age 18. Preventing the start of addiction in this vulnerable population should be a top priority.

In fact, there are encouraging signs of success with tobacco control. The prevalence of smoking for United States adults has hit a modern day nadir of 19%, which is a remarkable reduction from the 1955 peak of 57% for males and the 1965 peak of 34% for females. See Chapter 1: Disease Prevention & Health Promotion for additional material on smoking cessation techniques.

For those Americans who do not abuse tobacco, the most modifiable risk factors would be nutrition and physical activity. Epidemiologic studies suggest that fruit- and vegetable-rich diets lower risks of several gastrointestinal malignancies, including esophageal, stomach, and colon cancers. Excessive consumption of alcohol is linked to increased risks of head and neck cancers as well as cancers of the esophagus and liver. Lastly, being overweight is linked to several malignancies, including breast and uterine cancers in women and colorectal, esophageal, and kidney cancers in both men and women. More importantly, weight reduction can decrease the risks of these cancers.

Staging

The most commonly used staging system at the time of diagnosis is the TNM (Tumor, Nodes, Metastasis) system (see www.cancerstaging.org). Rules for staging for individual cancers are established and published by the American Joint Committee on Cancer (AJCC). Elements used for staging include tumor size and level of tumor invasion (T), absence or presence and extent of nodal metastases (N), and presence or absence of systemic metastases (M). Once the TNM designations have been determined, an overall stage is assigned, stage I, II, III, or IV. Clinical staging utilizes physical examination, laboratory and imaging tests as well as results from biopsies; pathologic staging relies on the results from surgery. In some instances, other classifications may be used for certain cancers such as the Ann Arbor staging system for lymphomas or the International Federation of Gynecologists and Obstetricans (FIGO) staging systems for gynecologic malignancies.

Other characteristics of cancers, not reflected in the TNM stage, may be used as another indicator of prognosis. Pathologic features seen on routine histologic examination for some cancers are very important; examples include the Gleason score for prostate cancer and the grade of sarcomas. Special tests done on cancer specimens can also be used to determine prognosis as well as treatment; examples include estrogen and progesterone status and the presence or absence of *HER-2/neu* for breast cancers. Chromosome analysis, now routinely done for patients with hematologic disorders and important in determining prognosis, can occasionally be useful for patients with solid tumors. For example, in patients with carcinoma of unknown primary origin, abnormal findings on chromosome 12 predict a response to chemotherapy and a better prognosis. In the future, as the pathways for oncogenesis and relationships of mutations to treatment and prognosis are better delineated, analysis for detection of chromosomal alterations and oncogene products will be increasingly incorporated into routine practice.

The Paraneoplastic Syndromes

The clinical manifestations of cancer are usually due to pressure effects of local tumor growth, infiltration or metastatic deposition of tumor cells in a variety of organs in the body, or certain systemic symptoms. General problems observed in many patients with advanced or widespread metastatic cancer include anorexia, malaise, weight loss, and sometimes fever. These characteristics must be considered when evaluating a patient with an undiagnosed illness. Except in the case of functioning tumors such as those of the endocrine glands, systemic symptoms of cancer usually are not specific, often consisting of weakness, anorexia, and weight loss. The term paraneoplastic refers to features of disease considered to be due to the remote effects of a cancer that cannot be attributed either to a cancer's direct invasive or metastatic properties and are often considered to be due to aberrant hormonal or metabolic effects not observed in a cancer's normal tissue equivalent. In the paraneoplastic syndromes, clinical findings may resemble those of primary endocrine, metabolic, hematologic, or neuromuscular disorders. At present, the mechanisms for such remote effects can be classified into three groups: (1) effects initiated by a tumor product (eg, carcinoid syndrome, ectopic hormone production), (2) effects of destruction of normal tissues by tumor (eg, hypercalcemia with osteolytic skeletal metastases), and (3) effects due to unknown mechanisms. In paraneoplastic syndromes associated with ectopic hormone production, tumor tissue itself secretes the hormone that produces the syndrome. Ectopic hormones secreted by neoplasms are often pro-hormones of higher molecular weight than those secreted by the more differentiated normal endocrine cell. Such ectopic hormone production by cancer cells is believed to result from activation of genes in the malignant cells that are suppressed in the normal tissue equivalent and in most somatic cells. Autocrine growth factors secreted by neoplastic cells may also result in paraneoplastic syndromes. Small cell lung cancer is the one type of cancer most likely to be associated with paraneoplastic syndromes.

The paraneoplastic syndromes are clinically important for the following reasons:

(1) They sometimes accompany relatively limited neoplastic growth and may provide the clinician with an early clue to the presence of certain types of cancer.

(2) The metabolic or toxic effects of the syndrome may constitute a more urgent hazard to the patient's life than the underlying cancer (eg, hypercalcemia, hyponatremia).

(3) Effective treatment of the tumor should be accompanied by resolution of the paraneoplastic syndrome and, conversely, recurrence of the cancer may be heralded by return of the systemic symptoms. In some instances, rapid response to cytotoxic chemotherapy may briefly increase the severity of the paraneoplastic syndrome in association with tumor lysis (eg, hyponatremia with inappropriate antidiuretic hormone excretion). In some instances the identical symptom complex (eg, hypercalcemia) may be induced by entirely different mechanisms. A single syndrome such as hypercalcemia may be due to any one of a variety of humoral factors, such as secretion of parathyroid hormone precursors or homologs, an osteoclast-activating factor (lymphotoxin), transforming growth factor- , or prostaglandins. Effective antitumor treatment usually results in return of serum calcium to normal.

Common paraneoplastic syndromes and endocrine secretions associated with functional cancers are summarized in Table 39–2.

Bronchogenic Carcinoma

Sunny Wang, MD, Mark S. Chesnutt, MD, James A. Murray, DO, Thomas J. Prendergast, MD

Essentials of Diagnosis

- New cough, or change in chronic cough.
- Dyspnea, hemoptysis, anorexia, weight loss.
- Enlarging nodule or mass; persistent opacity, atelectasis, or pleural effusion on chest radiograph or CT scan.
- Cytologic or histologic findings of lung cancer in sputum, pleural fluid, or biopsy specimen.

General Considerations

Lung cancer is the leading cause of cancer deaths in both men and women. The American Cancer Society estimated that there were 215,020 new diagnoses and 161,840 deaths from lung cancer in the United States in 2008, accounting for approximately 15% of new cancer diagnoses and 29% of all cancer deaths. More Americans die of lung cancer than of colorectal, breast, and prostate cancers combined. Lung cancer was a previously reportable disease until the widespread use of manufactured cigarettes in the 20th century. The causal connection between cigarettes and lung cancer is now established not only epidemiologically but also through identification of carcinogens in tobacco smoke and analysis of the effect of these carcinogens on specific oncogenes expressed in lung cancer. Even cigarette manufacturers no longer dispute the role of tobacco in this epidemic.

Cigarette smoking causes more than 90% of cases of lung cancer. Since the early 1990s, mortality from lung cancer fell among men while it increased among women and is only now peaking among women, reflecting changing patterns of tobacco use over the past 30 years (see Chapter 1: Disease Prevention & Health Promotion). Other environmental risk factors for the development of lung cancer include exposure to environmental tobacco smoke, radon gas (among uranium miners and in areas where radium in the soil causes significant indoor air contamination), asbestos (60- to 100-fold increased risk in smokers with asbestos exposure), metals (arsenic, chromium, nickel, iron oxide), and industrial carcinogens (bis-chloromethyl ether). A familial predisposition to lung cancer is recognized. Certain diseases are associated with an increased risk of lung cancer, including pulmonary fibrosis, chronic obstructive pulmonary disease, and sarcoidosis. Second primary lung cancers are more frequent in patients who survive their initial lung cancer.

The median age at diagnosis of lung cancer is 71; it is unusual under the age of 40. After the diagnosis of lung cancer is made, approximately 41% of patients survive 1 year. The combined 5-year survival rate for all stages of lung cancer is now approximately 15%, improved from 12% in 1974–1976.

Five histologic categories of bronchogenic carcinoma account for more than 90% of cases of primary lung cancer. **Squamous cell carcinoma** (20% of cases) arises from the bronchial epithelium, typically as a centrally located, intraluminal sessile or polypoid mass. Squamous cell tumors are more likely to present with hemoptysis and more frequently are diagnosed by sputum cytology. They spread locally and may be associated with hilar adenopathy and mediastinal widening on chest radiography. **Adenocarcinoma** (35–40% of cases) arises from mucus glands or, in the case of **bronchioloalveolar cell carcinoma** (2% of cases), from any epithelial cell within or distal to the terminal bronchioles. Adenocarcinomas usually present as peripheral nodules or masses. Bronchioloalveolar cell carcinoma spreads intra-alveolarly and may present as an infiltrate or as single or multiple pulmonary nodules. **Large cell carcinoma** (3–5% of cases) is a heterogeneous group of relatively undifferentiated tumors that share large cells and do not fit into other categories. Large cell carcinomas typically have rapid doubling times and an aggressive clinical course. They present as central or peripheral masses. Tumors that are not better differentiated on pathologic review other than carcinoma unspecified make up about 20–25% of cases. **Small cell carcinoma** (10–15% of cases) is a tumor of bronchial origin that typically begins centrally, infiltrating submucosally to cause narrowing or obstruction of the bronchus without a discrete luminal mass. Hilar and mediastinal abnormalities are common on chest radiography.

For purposes of staging and treatment, bronchogenic carcinoma is divided into small cell lung cancer (SCLC) and the other four types, conveniently labeled non–small cell lung cancer (NSCLC). This practical classification reflects different natural histories and different treatment. SCLC is prone to early hematogenous spread. It is rarely amenable to surgical resection and has a very aggressive course with a median survival (untreated) of 6–18 weeks. The four histologic categories comprising NSCLC spread more slowly. They may be cured in the early stages following resection, and they respond similarly to chemotherapy.

Clinical Findings

Lung cancer is symptomatic at diagnosis in 75–90% of patients. The clinical presentation depends on the type and location of the primary tumor, the extent of local spread, and the presence of distant metastases and any paraneoplastic syndromes.

Symptoms and Signs

Anorexia, weight loss, or asthenia occurs in 55–90% of patients presenting with a new diagnosis of lung cancer. Up to 60% of patients have a new cough or a change in a chronic cough; 6–31% have hemoptysis; and 25–40% complain of pain, sometimes nonspecific chest pain but often referable to bony metastases to the vertebrae, ribs, or pelvis. Local spread may cause endobronchial obstruction with atelectasis and postobstructive pneumonia, pleural effusion (12–33%), change in voice (compromise of the recurrent laryngeal nerve), superior vena cava syndrome (obstruction of the superior vena cava with supraclavicular venous engorgement), and Horner syndrome (ipsilateral ptosis, miosis, and anhidrosis from involvement of the inferior cervical ganglion and the paravertebral sympathetic chain). Distant metastases to the liver are associated with asthenia and weight loss. Brain metastases (10% in NSCLC, more common in adenocarcinoma, and 20–30% in SCLC) may present with headache, nausea, vomiting, seizures, or altered mental status.

Paraneoplastic syndromes are incompletely understood patterns of organ dysfunction related to immune-mediated or secretory effects of neoplasms. These syndromes occur in 10–20% of lung cancer patients. They may precede, accompany, or follow the diagnosis of lung cancer. They do not necessarily indicate metastatic disease. In patients with small cell carcinoma, the syndrome of inappropriate antidiuretic hormone (SIADH) will develop in 10–15%; in those with squamous cell carcinoma, hypercalcemia will develop in 10%. Digital clubbing is seen in up to 20% of patients at diagnosis (Plate 47). Other common paraneoplastic syndromes include increased ACTH production, anemia, hypercoagulability, peripheral neuropathy, and the Eaton-Lambert myasthenia syndrome. Their recognition is important because treatment of the primary tumor may improve or resolve symptoms even when the cancer is not curable.

Medicine. McGraw-Hill, 2009.)

Laboratory Findings

The diagnosis of lung cancer rests on examination of a tissue or cytology specimen. Sputum cytology is highly specific but insensitive; the yield is highest when there are lesions in the central airways. Thoracentesis (sensitivity 50–65%) can be used to establish a diagnosis of lung cancer in patients with malignant pleural effusions. If cytologic examination of an adequate sample (50–100 mL) of pleural fluid is nondiagnostic, the procedure should be repeated once; approximately 30% of the second samples are positive when the first sample is negative. If results remain negative, thoracoscopy is preferred to blind pleural biopsy. Fine-needle aspiration (FNA) of palpable supraclavicular or cervical lymph nodes is frequently diagnostic. Serum tumor markers are neither sensitive nor specific enough to aid in diagnosis.

Fiberoptic bronchoscopy allows visualization of the major airways, cytology brushing of visible lesions or lavage of lung segments with cytologic evaluation of specimens, direct biopsy of endobronchial abnormalities, blind transbronchial biopsy of the pulmonary parenchyma or peripheral nodules, and FNA biopsy of mediastinal lymph nodes. Diagnostic yield varies widely (10–90%) depending on the size of the lesion and its location. Recent advances include fluorescence bronchoscopy, which improves the ability to identify early endobronchial lesions; and endobronchial and transesophageal endoscopic ultrasound, both of which permit more accurate direction of FNA of mediastinal nodes. Transthoracic needle aspiration (TTNA) has a sensitivity between 50% and 97%. Mediastinoscopy, video-assisted thoracoscopic surgery (VATS), and thoracotomy are necessary in cases where less invasive techniques fail to yield a diagnosis.

Imaging

Nearly all patients with lung cancer have abnormal findings on chest radiography or CT scan. These findings are rarely specific for a particular diagnosis. Interpretation of characteristic findings in isolated nodules is described in Chapter 9: Pulmonary Disorders.

Special Examinations

Staging

Accurate staging (eTable 39–2.1) is crucial (1) to provide the clinician with information to guide treatment, (2) to provide the patient with accurate information regarding prognosis, and (3) to standardize entry criteria for clinical trials to allow interpretation of results.

eTable 39–2.1. TNM staging for lung cancer.

Stage	**T**	**N**	**M**	**Description**
0	Tis			Carcinoma in situ
IA	T1	N0	M0	Limited local disease without nodal or distant metastases
IB	T2	N0	M0	
IIA	T1	N1	M0	Limited local disease with ipsilateral hilar or peribronchial nodal involvement but not distant metastases or
IIB	T2	N1	M0	
	T3	N0	M0	Locally invasive disease without nodal or distant metastases
IIIA	T3	N1	M0	Locally invasive disease with ipsilateral or peribronchial nodal involvement but not distant metastases or
	T1–3	N2	M0	Limited or locally invasive disease with ipsilateral mediastinal or subcarinal nodal involvement but not distant metastases
IIIB	Any T	N3	M0	Any primary with contralateral mediastinal or hilar nodes, or ipsilateral scalene or supraclavicular nodes or
	T4	Any	M0	Unresectable local invasion with

		N		any degree of adenopathy but no distant metastases; malignant pleural effusion
IV	Any T	Any N	M1	Distant metastases

Primary Tumor (T)	
TX	Primary tumor cannot be assessed; or tumor proved by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy.
T0	No evidence of primary tumor.
Tis	Carcinoma in situ.
T1	A tumor 3 cm in greatest dimension, surrounded by lung or visceral pleura, and without evidence of invasion proximal to a lobar bronchus at bronchoscopy.
T2	A tumor > 3.0 cm in greatest dimension, or a tumor of any size that either involves a main bronchus (but is 2 cm distal to the carina), invades the visceral pleura, or has associated atelectasis or obstructive pneumonitis extending to the hilar region. Any associated atelectasis or obstructive pneumonitis must involve less than an entire lung.
T3	A tumor of any size with direct extension into the

	chest wall (including superior sulcus tumors), the diaphragm, the mediastinal pleura, or the parietal pericardium; or a tumor in the main bronchus < 2 cm distal to the carina without involving the carina; or associated atelectasis or obstructive pneumonitis of the entire lung.
T4	A tumor of any size with invasion of the mediastinum, heart, great vessels, trachea, esophagus, vertebral body, or carina; or with a malignant pleural or pericardial effusion; or with satellite tumor nodules within the ipsilateral lobe of the lung containing the primary tumor.
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed.
N0	No demonstrable metastasis to regional lymph nodes.
N1	Metastasis to lymph nodes in the peribronchial or the ipsilateral hilar region, or both, including direct extension.
N2	Metastasis to ipsilateral mediastinal lymph nodes and/or subcarinal lymph nodes.
N3	Metastasis to contralateral mediastinal lymph nodes, contralateral hilar lymph nodes, ipsilateral or contralateral scalene or supraclavicular lymph nodes.
Distant Metastases (M)	

MX	Presence of distant metastasis cannot be assessed.
M0	No (known) distant metastasis.
M1	Distant metastasis present.

Adapted, with permission, from Mountain CF. Revisions in the international system for staging lung cancer. Chest. 1997;111:1710.

There are two essential principles of staging NSCLC. First, the more extensive the disease, the worse the prognosis; second, surgical resection offers the best hope for cure. Staging of NSCLC uses two integrated systems. The **TNM international staging system** attempts a physical description of the neoplasm: T describes the size and location of the primary tumor; N describes the presence and location of nodal metastases; and M refers to the presence or absence of distant metastases. These TNM stages are grouped into prognostic categories (stages I–IV) using the results of clinical trials. This classification is used to guide therapy. Many patients with stage I and stage II disease are cured through surgery. Patients with stage IIIB and stage IV disease do not benefit from surgery (Table 39–3). Patients with stage IIIA disease have locally invasive disease that may benefit from surgery in certain circumstances.

Table 39–3. Approximate survival rates following

treatment for lung cancer.		
Non–Small Cell Lung Cancer: Mean 5-Year Survival Following Resection		
Stage	**Clinical Staging**	**Surgical Staging**
IA (T1N0M0)	60%	74%
IB (T2N0M0)	38%	61%
IIA (T1N1M0)	34%	55%
IIB (T2N1M0, T3N0M0)	23%	39%
IIIA	9–13%	22%
IIIB[1]	3–12%	
IV[1]	4%	
Small Cell Lung Cancer: Survival Following Chemotherapy		
Stage	**Mean 2-Year Survival**	**Median Survival**
Limited	15–20%	14–20 months
Extensive	< 3%	8–13 months

[1] Independent of therapy, generally not surgical patients.

Data from multiple sources. Modified and reproduced, with permission, from Reif MS et al. Evidence-based medicine in the treatment of non-small cell cancer. Clin Chest Med. 2000;21:107.

SCLC is not staged using the TNM system because micrometastases are assumed to be present on diagnosis. SCLC is divided into two categories: **limited disease** (30%), when the tumor is limited to the unilateral hemithorax (including contralateral mediastinal nodes); or **extensive disease** (70%), when the tumor extends beyond the hemithorax (including pleural effusion). This scheme also guides therapy. Patients with limited SCLC benefit from thoracic radiation therapy in addition to chemotherapy as well as prophylactic cranial radiation therapy.

For both SCLC and NSCLC, staging begins with a thorough history and physical examination. A complete examination is essential to exclude obvious metastatic disease to lymph nodes, skin, and bone. A detailed history is essential because the patient's performance status is a powerful predictor of disease course. All patients should have measurement of a complete blood count, electrolytes including calcium, creatinine, liver tests including lactate dehydrogenase (LD) and alkaline phosphatase, and a chest radiograph. Further evaluation will follow the results of these tests. In general, screening asymptomatic lung cancer patients with MRI of the brain, radionuclide bone imaging, and abdominal CT imaging does not change patient outcomes. These tests should be targeted to specific symptoms and signs.

NSCLC patients being considered for surgery require meticulous evaluation to identify those with resectable disease. CT imaging is the most important modality for staging candidates for resection. A chest CT scan precisely defines the size of parenchymal lesions and identifies atelectatic lung or pleural effusions. However, CT imaging is less accurate at determining invasion of the chest wall (sensitivity 62%) or mediastinum (sensitivity 60–75%). The sensitivity and specificity of CT imaging for identifying lung cancer metastatic to the mediastinal lymph nodes are 57% (49–66%) and 82% (77–86%), respectively. Therefore, chest CT imaging does not provide definitive information on staging. CT imaging does help in making the decision about whether to proceed to resection of the primary tumor and sample the mediastinum at thoracotomy (common if there are no lymph nodes > 1 cm) or to use TTNA, mediastinoscopy, esophageal ultrasound with transesophageal needle aspiration, or limited thoracotomy to biopsy suspected metastatic disease (common where there are lymph nodes > 1–2 cm).

Positron emission tomography (PET) using 2-[^{18}F]fluoro-2-deoxyglucose (FDG) is a noninvasive alternative for identifying metastatic foci in the mediastinum or distant sites. The sensitivity and specificity of PET for detecting mediastinal spread of primary lung cancer depend on the size of mediastinal nodes or masses. When only normal-sized (< 1 cm) mediastinal lymph nodes are present, the sensitivity and specificity of PET for tumor involvement of nodes are 74% and 96%, respectively. When CT shows enlarged (> 1 cm) lymph nodes, the sensitivity and specificity are 95% and 76%, respectively.

PET imaging is being incorporated into diagnostic algorithms that take advantage of both its positive and negative predictive values. Many lung cancer specialists find PET most useful to confirm lack of metastatic disease in NSCLC patients who are candidates for surgical resection. There is also evidence that PET imaging reduces futile thoracotomies by identifying mediastinal and distant metastases in patients with NSCLC. Disadvantages of PET imaging include limited resolution below 1 cm; the expense of FDG; limited availability; and false-positive scans due to sarcoidosis, tuberculosis, or fungal infections.

Preoperative assessment

See Chapter 3: Preoperative Evaluation amp;Perioperative Management.

Pulmonary function testing

Many patients with NSCLC have moderate to severe chronic lung disease that increases the risk of perioperative complications as well as long-term pulmonary insufficiency following lung resection. All patients considered for surgery require spirometry. In the absence of other comorbidities, patients with good lung function (preoperative FEV_1 2 L) are at low risk for complications from lobectomy or pneumonectomy. If the FEV_1 is less than 2 L, then an estimated postoperative FEV_1 should be calculated. The postresection FEV_1 may be estimated from considering preoperative spirometry and the amount of lung to be resected; in severe obstructive disease, a quantitative lung perfusion scan may improve the estimate. A predicted post-lung resection FEV_1 > 800 mL (or > 40% of predicted FEV_1) is associated with a low incidence of perioperative complications. High-risk patients include those with a predicted postoperative FEV_1 < 700 mL (or < 40% of predicted FEV_1). In these patients and in those with borderline spirometry, cardiopulmonary exercise testing may be helpful. A maximal oxygen uptake (O_2) of > 15 mL/kg/min identifies patients with an acceptable incidence of complications and mortality. Patients with a O_2 of < 10 mL/kg/min have a very high mortality rate at thoracotomy. Hypoxemia and hypercapnia are not independent predictors of outcome.

Screening

The optimal screening of smokers for lung cancer is unclear. Both chest radiographs and analysis of expectorated sputum is ineffective. Recent studies have tried to assess the role of chest CT scans. A study by Bach et al showed that CT screening of populations increases the diagnosis of lung cancer but does not reduce the risk of advanced lung cancer or reduce mortality. The investigators of the International Early Lung Cancer Action Program, however, suggested that there is a role for screening with chest CT. These studies highlight how complex and confusing the analysis of screening for lung cancer can be. At the present time, there are inadequate data to recommend the use of chest CT to screen smokers for lung cancer. The National Lung Screening Trial is an ongoing National Cancer Institute funded multicenter trial to determine whether using low-dose helical CT to screen current or former heavy smokers for lung cancer will improve mortality in this population. Information is available at http://www.cancer.gov/NLST/.

Treatment

Non–Small Cell Carcinoma

Cure of NSCLC is unlikely without resection. Therefore, the initial approach to the patient is determined by the answers to two questions: (1) Is complete surgical resection technically feasible? (2) If yes, is the patient able to tolerate the surgery with acceptable morbidity and mortality? Clinical features that preclude complete resection include extrathoracic metastases or a malignant pleural effusion; or tumor involving the heart, pericardium, great vessels, esophagus, recurrent laryngeal or phrenic nerves, trachea, main carina, or contralateral mediastinal lymph nodes. Accordingly, stage I and stage II patients are treated with surgical resection where possible. Stage II, and possibly a subset of stage IB, are additionally recommended to receive adjuvant chemotherapy. Stage IIIA patients have poor outcomes when treated with resection alone. They should be referred to multimodality protocols, including chemotherapy and radiotherapy. Stage IIIB patients treated with concurrent chemotherapy and radiation therapy have improved survival. Selected stage IIIB patients who undergo resection after multimodality therapy have shown long-term survival and may be cured. Stage IV patients are treated with chemotherapy or symptom-based palliative therapy, or both (see below).

Surgical approach affects outcome. The North American Lung Cancer Study Group conducted a prospective trial of stage IA patients randomized to lobectomy versus limited resection. They reported a threefold increased rate of local recurrence in the limited resection group ($P =$

0.008) and a trend toward an increase in overall death rate (increase of 30%, *P* = 0.08) and increase in death rate due to cancer (increase of 50%, *P* = 0.09), compared with patients receiving lobectomy. There are inadequate outcome data on which to base a comparison of VATS with standard thoracotomy. Radiation therapy following surgery improves local control but does not improve survival.

Patients with small early-stage primary lung cancers who are not candidates for surgery because of significant comorbidity or other surgical contraindication may be candidates for stereotactic radiosurgery or radiotherapy. This technology, which is composed of multiple non-parallel radiation beams that converge, allows the delivery of a relatively large dose of radiation to a small, well-defined target. Referral to a radiation oncologist is appropriate in such cases. Patients with locally advanced disease (stages IIIA and IIIB) who are not surgical candidates have improved survival when treated with concurrent chemotherapy and radiation therapy compared with no therapy, radiation alone, or even sequential chemotherapy and radiation.

Neoadjuvant chemotherapy consists of giving antineoplastic drugs in advance of surgery or radiation therapy. There is no consensus on the impact of neoadjuvant therapy on survival in stage I and stage II

NSCLC. Such therapy is not recommended outside of ongoing clinical trials. Neoadjuvant therapy is more widely used in selected patients with stage IIIA or stage IIIB disease. Some studies suggest a survival advantage. This remains an area of active research.

Adjuvant chemotherapy consists of administering antineoplastic drugs following surgery or radiation therapy. Cisplatin-containing regimens have been shown to confer an overall survival benefit in at least stage II disease and possibly a subset of stage IB disease. The Lung Adjuvant Cisplatin Evaluation Collaborative Group just published a meta-analysis of the five largest cisplatin-based adjuvant trials. They reported a 5% absolute benefit in 5-year overall survival with a cisplatin-containing doublet regimen following surgery ($P = 0.005$) in patients with at least stage II disease. There is no evidence of a survival benefit, and it may even be detrimental in patients with poor performance status (Eastern Cooperative Oncology Group Score 2). Novel targeted agents with less toxicity are in clinical trials, and gene expression profiling has shown promise in defining a subset of patients with stage IA disease who may benefit from adjuvant therapy.

Although not curative, chemotherapy has been shown in multiple clinical trials to provide a modest increase in overall survival in patients with stage IIIB and stage IV

NSCLC and good performance status compared with supportive care alone, with median survival increased from 5 months to a range of 7–11 months. Palliative chemotherapy also leads to improved quality of life and symptom control. A platinum-based regimen is most often used to treat such cases, with a multitude of active agents from which to choose. A recent randomized trial has now shown a survival benefit of adding bevacizumab (a monoclonal antibody to vascular endothelial growth factor [VEGF]) to a traditional platinum doublet regimen. Another targeted agent, erlotinib (an epidermal growth factor receptor [EGFR] tyrosine kinase inhibitor) has been shown to improve survival as second-line treatment for advanced NSCLC and is especially effective in cases affecting women, nonsmokers, and persons of Asian ethnicity as well as cases involving adenocarcinoma and bronchioalveolar carcinoma histology.

Small Cell Carcinoma

Response rates of SCLC to cisplatin and etoposide are excellent: 80–90% response in limited-stage disease (50–60% complete response), and 60–80% response in extensive stage disease (15–20% complete response). However, remissions tend to be short-lived with a median duration of 6–8 months. Once the disease has recurred, median survival is 3–4 months. Overall 2-year survival is 20–40% in limited-stage disease and less than 5% in extensive-stage disease. Thoracic radiation therapy improves survival in patients with limited SCLC but not those with extensive disease. There is a high rate brain metastasis in patients with SCLC, even following a good response to chemotherapy, because chemotherapy does not adequately penetrate the blood-brain barrier. Prophylactic cranial irradiation has been shown to decrease the incidence of central nervous system disease and improve survival in patients with limited stage disease who respond to chemotherapy and possibly in a subset of patients with extensive stage disease who have had an excellent response to chemotherapy.

Occasionally, a patient may have a peripheral nodule resected that turns out to be SCLC. Five-year survival following resection of the equivalent of stage I and stage II SCLC is higher than in patients treated with chemotherapy.

Palliative Therapy

Photoresection with the Nd:YAG laser is sometimes performed on central tumors to relieve endobronchial obstruction, improve dyspnea, and control hemoptysis. External beam radiation therapy is also used to control dyspnea and hemoptysis, pain from bony metastases, obstruction from superior vena cava syndrome, and symptomatic brain metastases. Resection of a *solitary* brain metastasis improves quality of life when combined with radiation therapy, and if there is no evidence of other metastatic disease, it may improve survival. Intraluminal radiation (brachytherapy) is an alternative approach to endobronchial disease. Pain syndromes are very common in advanced disease. As patients approach the end of life, meticulous efforts at pain control are essential (see Chapter 5: Palliative Care & Pain Management). Consultation with or referral to a palliative care specialist is recommended in advanced disease to aid in symptom management and to facilitate referrals to hospice programs.

Prognosis

The overall 5-year survival rate for lung cancer is 15%. Predictors of survival are the type of tumor (SCLC versus NSCLC), the stage of the tumor, and the patient's performance status, including weight loss in the past 6 months. These are independent predictors in both early and late stage disease. Most data suggest that there is no difference among non–small cell carcinomas when adjusted for stage and performance status.

Pulmonary Metastases

Pulmonary metastasis results from the spread of an extrapulmonary malignant tumor through vascular or lymphatic channels or by direct extension. Almost any cancer can metastasize to the lung. Metastases usually occur via the pulmonary artery and typically present as multiple nodules or masses on chest radiography. The radiographic differential diagnosis of multiple pulmonary nodules also includes pulmonary arteriovenous malformation, pulmonary abscesses, granulomatous infection, sarcoidosis, rheumatoid nodules, and Wegener granulomatosis. Metastases to the lungs are found in 20–55% of patients dying of various malignancies. Most are intraparenchymal. Endobronchial metastases occur in less than 5% of patients dying of nonpulmonary cancer; carcinoma of the kidney, breast, colon, and cervix and malignant melanoma are the most likely primary tumors.

Lymphangitic carcinomatosis denotes diffuse involvement of the pulmonary lymphatic network by primary or metastatic lung cancer, probably a result of extension of tumor from lung capillaries to the lymphatics. **Tumor embolization** from extrapulmonary cancer (renal cell carcinoma, hepatocellular carcinoma, choriocarcinoma) is an uncommon route for tumor spread to the lungs. Metastatic cancer may also present as a malignant pleural effusion.

Clinical Findings

Symptoms and Signs

Symptoms are uncommon but include cough, hemoptysis and, in advanced cases, dyspnea and hypoxemia. Symptoms are more often referable to the site of the primary tumor.

Laboratory Findings

The diagnosis of metastatic cancer involving the lungs is usually established by identifying a primary tumor. Appropriate studies should be ordered if there is a suspicion of any primary cancer, such as breast, thyroid, testis, colorectal, or prostate, for which specific treatment is available. For example, an elevated prostate-specific antigen (PSA) may indicate prostate cancer, carcinoembryonic antigen (CEA) tests for colorectal or pancreatic cancer, and -human chorionic gonadotropin (HCG) and -fetoprotein (AFP) test for testicular cancer. Based on the clinical setting, certain imaging studies should be ordered (see below). If the history, physical examination, and initial studies fail to reveal the site of the primary tumor, attention is better focused on the lung, where tissue samples obtained by bronchoscopy, percutaneous needle biopsy, or thoracotomy may establish the histologic diagnosis and suggest the most likely primary cancer. Occasionally, cytologic studies of pleural fluid or pleural biopsy reveal the diagnosis. Sputum cytology is rarely helpful.

If the initial histologic review does not reveal a primary diagnosis, immunohistochemical staining should be done on the biopsy specimen. For example, PSA and thyroglobulin staining are highly specific for prostate and thyroid cancer, respectively. Thyroid transcription factor-1 (TTF-1) is relatively specific for primary lung adenocarcinoma, while also positive for small cell carcinoma and thyroid carcinoma. An adenocarcinoma that demonstrates negative TTF-1 staining strongly suggests a nonpulmonary primary cancer. Positive estrogen receptor (ER) and progesterone receptor (PR) stains suggest primary breast cancer. Finally, the pattern of cytokeratin 7 and 20 staining can also help point toward a primary diagnosis.

Imaging

Chest radiographs usually show multiple spherical densities with sharp margins. The size of metastatic lesions varies from a few millimeters (miliary densities) to large masses. Nearly all are less than 5 cm in diameter. The lesions are usually bilateral, pleural or subpleural in location, and more common in lower lung zones. Cavitation suggests primary squamous cell tumor; calcification suggests osteosarcoma. Lymphangitic spread and solitary pulmonary nodule are less common radiographic presentations of pulmonary metastasis. Conventional chest radiography is less sensitive than CT scan in detecting pulmonary metastases. Mammography should be considered in women unless one has been performed recently to search for possible primary breast cancer. CT imaging of the chest, abdomen, and pelvis may reveal the site of a primary tumor and will help determine feasibility of surgical resection of the metastatic lung tumors. PET scan may also help in identifying the site of a primary cancer or identifying other areas of extrathoracic metastasis.

Treatment

Once the diagnosis has been established, management consists of treatment of the primary neoplasm and any pulmonary complications. Surgical resection of a *solitary* pulmonary nodule is often prudent in the patient with known current or previous extrapulmonary cancer. Local resection of one or more pulmonary metastases is feasible in a few carefully selected patients with various sarcomas and carcinomas (breast, testis, colon, kidney, and head and neck). Surgical resection should be considered only if the primary tumor is under control, if the patient is a good surgical risk, if all of the metastatic tumor can be resected, if nonsurgical approaches are not available, and if there are no metastases elsewhere in the body. Relative contraindications to resection of pulmonary metastases include (1) malignant melanoma primary, (2) requirement for pneumonectomy, and (3) pleural involvement. Data from the International Registry of Lung Metastases report an overall 5-year survival rate of 36% and 10-year survival rate of 26% after complete resection of pulmonary metastases. For patients with progressive disease, diligent attention to palliative care is essential (see Chapter 5: Palliative Care & Pain Management).

Mesothelioma

Essentials of Diagnosis

- Unilateral, nonpleuritic chest pain and dyspnea.
- Distant (> 20 years earlier) history of exposure to asbestos.
- Pleural effusion or pleural thickening or both on chest radiographs.
- Malignant cells in pleural fluid or tissue biopsy.

General Considerations

Mesotheliomas are primary tumors arising from the surface lining of the pleura (80% of cases) or peritoneum (20% of cases). About three-fourths of pleural mesotheliomas are diffuse (usually malignant) tumors, and the remaining one-fourth are localized (usually benign). Men outnumber women by a 3:1 ratio. Numerous studies have confirmed the association of **malignant pleural mesothelioma** with exposure to asbestos (particularly the crocidolite form). The lifetime risk to asbestos workers of developing malignant pleural mesothelioma is as high as 10%. Sixty to 80 percent of patients with malignant mesothelioma report a history of asbestos exposure. The latent period between exposure and onset of symptoms ranges from 20 to 40 years. The clinician should inquire about asbestos exposure through mining, milling, manufacturing, shipyard work, insulation, brake linings, building construction and demolition, roofing materials, and a variety of asbestos products (pipe, textiles, paint, tile, gaskets, panels). Although cigarette smoking significantly increases the risk of bronchogenic carcinoma in asbestos workers and aggravates asbestosis, there is no association between smoking and mesothelioma.

Clinical Findings

Symptoms and Signs

The mean age at onset of symptoms of malignant pleural mesothelioma is about 60 years. Symptoms include the insidious onset of shortness of breath, nonpleuritic chest pain, and weight loss. Physical findings include dullness to percussion, diminished breath sounds and, in some cases, digital clubbing.

Laboratory Findings

Pleural fluid is exudative and often hemorrhagic. Cytologic tests of pleural fluid are often negative. VATS biopsy is usually necessary to obtain an adequate specimen for histologic diagnosis; even then, distinction from benign inflammatory conditions and from metastatic adenocarcinoma may be difficult. The histologic variants of malignant pleural mesothelioma are epithelial and fibrous (sarcomatous). Special stains and electron microscopy may be needed to confirm the diagnosis.

Imaging

Radiographic abnormalities consist of nodular, irregular, unilateral pleural thickening and varying degrees of unilateral pleural effusion. Sixty percent of patients have right-sided disease, while only 5% have bilateral involvement. There may be scoliosis toward the side of the lesion. CT scan helps demonstrate the extent of pleural involvement.

Complications

Malignant pleural mesothelioma progresses rapidly as the tumor spreads along the pleural surface to involve the pericardium, mediastinum, and contralateral pleura. The tumor may eventually extend beyond the thorax to involve abdominal lymph nodes and organs. Progressive pain and dyspnea are characteristic. Local invasion of thoracic structures may cause superior vena cava syndrome, hoarseness, Horner syndrome, and dysphagia. Paraneoplastic syndromes associated with mesothelioma include thrombocytosis, hemolytic anemia, disseminated intravascular coagulopathy, hypercalcemia, and migratory thrombophlebitis.

Treatment

Surgery, radiotherapy, chemotherapy, and a combination of methods are attempted, but treatments are generally unsuccessful. Pleurectomy and decortication (surgical stripping of the pleura and pericardium from apex of the lung to diaphragm) is one surgical approach but does not improve survival outcome even with adjuvant therapy. Some surgeons favor a trimodality approach with extrapleural pneumonectomy, adjuvant radiation, and chemotherapy, arguing that it prolongs survival in highly selected patients. Extrapleural pneumonectomy is a radical surgical procedure involving removal of the ipsilateral lung, parietal and visceral pleura, pericardium, and most of the hemi-diaphragm. However, the limited data for extrapleural pneumonectomy comes from retrospective studies and case series, where the patients are younger, have early-stage disease, have epithelial histology, and lack extrapleural nodal disease. In advanced unresectable cases, palliative chemotherapy with cisplatin and pemetrexed can extend survival as well as improve quality of life. Drainage of pleural effusions, pleurodesis, radiation therapy, and even surgical resection may offer palliative benefit in some patients.

Prognosis

Most patients die of respiratory failure and complications of local extension. Median survival time from onset of symptoms ranges from 4 months in extensive disease to 16 months in localized disease. Five-year survival is less than 5%.

Hepatocellular Carcinoma

Lawrence S. Friedman, MD

Essentials of Diagnosis

- In Western countries, usually a complication of cirrhosis.
- Characteristic CT and MRI features and elevated serum -fetoprotein may obviate the need for a confirmatory biopsy.

General Considerations

Malignant neoplasms of the liver that arise from parenchymal cells are called hepatocellular carcinomas; those that originate in the ductular cells are called cholangiocarcinomas.

Hepatocellular carcinomas are associated with cirrhosis in 80% of cases. Incidence rates are rising rapidly (twofold since 1978) in the United States and other Western countries, presumably because of the increasing prevalence of cirrhosis caused by chronic hepatitis C infection and nonalcoholic fatty liver disease. In Western countries, risk factors for hepatocellular carcinoma in patients known to have cirrhosis are male gender, age > 55 years (although there has been an increase in the number of younger cases), Asian or Hispanic ethnicity, family history in a first-degree relative, overweight, obesity, diabetes mellitus, hypothyroidism, HCV infection, HBsAg and anti-HBc positivity, prothrombin time < 75% of control, low platelet count, and an elevated serum transferrin saturation. In Africa and most of Asia, hepatitis B is of major etiologic significance, whereas in Western countries and Japan, hepatitis C (particularly genotype 1b and sometimes in combination with "occult" HBV infection) and alcoholic cirrhosis are the most common risk factors. Other associations include hemochromatosis (and possibly the *C282Y* carrier state), aflatoxin exposure (associated with mutation of the *TP53* gene), $_1$-antiprotease ($_1$-antitrypsin) deficiency, and tyrosinemia. Evidence for an association with long-term use of oral contraceptives is inconclusive. Coffee consumption appears to be protective. The fibrolamellar variant of hepatocellular carcinoma occurs in young women and is characterized by a distinctive histologic picture, absence of risk factors, and indolent course. Vinyl chloride exposure is associated with angiosarcoma of the liver.

Clinical Findings

Symptoms and Signs

The presence of a hepatocellular carcinoma may be unsuspected until there is deterioration in the condition of a cirrhotic patient who was formerly stable. Cachexia, weakness, and weight loss are associated symptoms. The sudden appearance of ascites, which may be bloody, suggests portal or hepatic vein thrombosis by tumor or bleeding from the necrotic tumor.

Physical examination may show tender enlargement of the liver, occasionally with a palpable mass. In Africa, the typical presentation in young patients is a rapidly expanding abdominal mass. Auscultation may reveal a bruit over the tumor or a friction rub when the process has extended to the surface of the liver.

Laboratory Findings

Laboratory tests may reveal leukocytosis, as opposed to the leukopenia that is frequently encountered in cirrhotic patients. Anemia is common, but a normal or elevated hematocrit may be found in up to one-third of patients owing to elaboration of erythropoietin by the tumor. Sudden and sustained elevation of the serum alkaline phosphatase in a patient who was formerly stable is a common finding. HBsAg is present in a majority of cases in endemic areas, whereas in the United States anti-HCV is found in up to 40% of cases. -Fetoprotein levels are elevated in up to 70% of patients with hepatocellular carcinoma in Western countries (although the sensitivity is lower in blacks); however, mild elevations are also often seen in patients with chronic hepatitis. Serum levels of des-gamma-carboxy prothrombin are elevated in up to 90% of patients with hepatocellular carcinoma, but they may also be elevated in patients with vitamin K deficiency, chronic hepatitis, and metastatic cancer. The L3 glycoform of -fetoprotein (AFP-L3) is under study. Cytologic study of ascitic fluid rarely reveals malignant cells.

Imaging

Multiphasic helical CT scanning and MRI with contrast enhancement are the preferred imaging studies for determining the location and vascularity of the tumor. Lesions smaller than 2 cm may be difficult to characterize. Arterial phase enhancement of the lesion followed by delayed hypointensity ("washout") is most specific for hepatocellular carcinoma. Ultrasound is less sensitive and operator dependent but is used to screen for hepatic nodules in high-risk patients. Contrast-enhanced ultrasound has a sensitivity and specificity approaching those of arterial phase helical CT but, unlike CT and MRI, cannot image the entire liver during the short duration of the arterial phase. In selected cases, endoscopic ultrasonography may be useful. PET is under study.

Liver Biopsy and Staging

Liver biopsy is diagnostic, although seeding of the needle tract by tumor is a potential risk (1–3%). Biopsy can be deferred if imaging studies and -fetoprotein levels are diagnostic (eg, serum -fetoprotein > 200 ng/mL and a hypervascular mass lesion > 2 cm on imaging of a cirrhotic liver) or if surgical resection is planned. Staging in the TNM classification includes the following definitions: T0: no evidence of primary tumor; T1: solitary tumor without vascular invasion; T2: solitary tumor with vascular invasion or multiple tumors none more than 5 cm; T3: multiple tumors more than 5 cm or tumor involving a major branch of the portal or hepatic vein; and T4: tumors with direct invasion of adjacent organs other than the gallbladder or with perforation of the visceral peritoneum. Alternative staging systems also incorporate liver function, tumor aggressiveness and growth rate, general health of the patient, and treatment. The BCLC (Barcelona Clinic Liver Cancer) staging system is now preferred and includes the Child-Turcotte-Pugh stage, tumor stage, and liver function and has the advantage of linking overall stage with preferred treatment modalities and with an estimation of life expectancy.

Screening & Prevention

In the patient with chronic hepatitis B or cirrhosis caused by HCV or alcohol, surveillance for the development of hepatocellular carcinoma is recommended. Although the standard approach is -fetoprotein testing and ultrasonography every 6 months, the value of -fetoprotein screening has been questioned because of its low sensitivity. The risk of hepatocellular carcinoma in a patient with cirrhosis is 3–5% a year. The diagnosis of hepatocellular carcinoma is established (without the need for biopsy) for lesions > 2 cm when characteristic arterial hypervascularity is demonstrated on both helical CT and MRI (or on either CT or MRI if the serum -fetoprotein level is higher than 200 mg/L). In a population of patients with cirrhosis, over 60% of nodules < 2 cm in diameter detected on a screening ultrasound prove to be hepatocellular carcinoma. Mass vaccination programs against HBV in developing countries are leading to reduced rates of hepatocellular carcinoma. Successful treatment of hepatitis C in patients with cirrhosis reduces the subsequent risk of hepatocellular carcinoma.

Treatment

Surgical resection of solitary hepatocellular carcinomas may result in cure if liver function is preserved (Child-Turcotte-Pugh class A or possibly B) and portal vein thrombosis is not present. Laparoscopic liver resection has been performed in selected cases. Treatment of underlying chronic viral hepatitis, adjuvant chemotherapy, and adaptive immunotherapy may lower postsurgical recurrence rates. Liver transplantation may be appropriate for small unresectable tumors in a patient with advanced cirrhosis, with reported 5-year survival rates of up to 75%. The recurrence-free survival may be better for liver transplantation than for resection in patients with well-compensated cirrhosis and small tumors (one tumor < 5 cm or three or fewer tumors each < 3 cm in diameter [Milan criteria]). Patients with stage 2 hepatocellular carcinoma receive an additional 22 points on their Model for End-Stage Liver Disease (MELD) score (see Chapter 16: Liver, Biliary Tract, & Pancreas Disorders), markedly increasing their chances of a transplant. However, liver transplantation is often impractical because of the donor organ shortage and living donor liver transplantation may be considered in these cases. Patients with larger tumors (3–5 cm), a serum -fetoprotein level 455 ng/mL, or a MELD score 20 have poor posttransplantation survival. Chemotherapy, hormonal therapy with tamoxifen, and long-acting octreotide have not been shown to prolong life, but transarterial chemoembolization (TACE), transarterial chemoinfusion (TACI), and transarterial radioembolization (TARE) via the hepatic artery are palliative and may prolong survival in patients with a large or multifocal tumor in the absence of extrahepatic spread. TACI and TARE are suitable for patients with portal vein thrombosis. Injection of absolute ethanol into, radiofrequency ablation of, cryotherapy of, or microwave ablation of small tumors (< 2 cm) may prolong survival in patients who are not candidates for resection; these interventions may provide a "bridge" to liver transplantation. Radiofrequency ablation is superior to ethanol injection for tumors > 2 cm in diameter and can be performed after TACE in select cases. Sorafenib (an oral multikinase inhibitor of Raf kinase, the VEGF, and the platelet-derived growth factor receptor [and others]), prolongs median survival as well as the time to radiologic progression by 3 months in patients with advanced hepatocellular carcinoma; sorafenib is the standard of care in these patients. New chemotherapy and radiation therapy techniques ("radioembolization") and novel biologic approaches (eg, bortezomib, a proteasome inhibitor; antiangiogenesis agents; other inhibitors of growth-factor signaling; and gene therapy) are under study. For patients whose disease progresses despite treatment or who present with advanced tumors, vascular invasion, or extrahepatic spread, meticulous efforts at palliative care are essential (see Chapter 5: Palliative Care & Pain Management). Severe pain may develop in such patients due to expansion of the liver capsule by the tumor and requires concerted efforts at pain management, including the use of opioids (see Chapter 5: Palliative Care & Pain Management).

Prognosis

In the United States, overall 1- and 5-year survival rates for patients with hepatocellular carcinoma are 23% and 5%, respectively. Five-year survival rates rise to 56% for patients with localized resectable disease (T1, T2, selected T3 and T4; N0; M0) but are virtually nil for those with localized unresectable or advanced disease. The fibrolamellar variant has a better prognosis than conventional hepatocellular carcinoma, with a 5-year survival rate of up to 75% following resection.

When to Refer

All patients with hepatocellular carcinoma should be referred to a specialist.

When to Admit

- Complications of cirrhosis.
- Severe pain.
- For surgery and other interventions.

Carcinoma of the Biliary Tract

Essentials of Diagnosis

- Presents with obstructive jaundice, usually painless, often with dilated biliary tree.
- Pain is more common in gallbladder carcinoma than cholangiocarcinoma.
- A Courvoisier (dilated) gallbladder may be detected.
- Diagnosis by cholangiography with biopsy and

brushings for cytology.

General Considerations

Carcinoma of the gallbladder occurs in approximately 2% of all people operated on for biliary tract disease. It is notoriously insidious, and the diagnosis is often made unexpectedly at surgery. Cholelithiasis (often large, symptomatic stones) is usually present. Other risk factors are chronic infection of the gallbladder with *Salmonella typhi*, gallbladder polyps over 1 cm in diameter, mucosal calcification of the gallbladder (porcelain gallbladder), and anomalous pancreaticobiliary ductal junction. Genetic factors include K-*ras* and *TP53* mutations. Spread of the cancer—by direct extension into the liver or to the peritoneal surface—may be the initial manifestation. The TNM classification includes the following stages: Tis, carcinoma in situ; T1a, tumor invades lamina propria, and T1b, tumor invades muscle layer; T2, tumor invades perimuscular connective tissue, no extension beyond serosa (visceral peritoneum) or into liver; T3, tumor perforates the serosa or directly invades the liver or adjacent organ or structure; T4, tumor invades the main portal vein or hepatic artery or invades multiple extrahepatic organs or structures; N1, regional lymph node metastasis; and M1, distant metastasis.

Carcinoma of the bile ducts (cholangiocarcinoma) accounts for 3% of all cancer deaths in the United States.

It is more prevalent in persons aged 50–70, with a slight male predominance. Two-thirds arise at the confluence of the hepatic ducts (Klatskin tumors), and one-fourth arise in the distal extrahepatic bile duct; the remainder are intrahepatic (peripheral), the incidence of which has risen dramatically since the 1970s. Staging is as follows: T1, solitary tumor without vascular invasion; T2, solitary tumor with vascular invasion or multiple tumors 5 cm; T3, multiple tumors > 5 cm or involving major branch of portal or hepatic veins; T4, tumor invading adjacent organ (except gallbladder) or perforation of visceral peritoneum; N1, regional lymph node metastasis; and M1, distant metastasis. Other staging systems consider tumor extent, vascular encasement, and hepatic lobe atrophy. The frequency of carcinoma in persons with choledochal cysts has been reported to be over 14% at 20 years, and surgical excision is recommended. There is an increased incidence in patients with bile duct adenoma; biliary papillomatosis; Caroli disease; a biliary-enteric anastomosis; ulcerative colitis, especially those with primary sclerosing cholangitis; biliary cirrhosis; diabetes mellitus; hyperthyroidism; chronic pancreatitis; heavy alcohol consumption; and past exposure to thorotrast, a contrast agent. In southeast Asia, hepatolithiasis and infection of the bile ducts with helminths *(Clonorchis sinensis, Opisthorchis viverrini)* are associated with chronic cholangitis and an increased risk of cholangiocarcinoma.

Hepatitis C virus infection, cirrhosis, HIV infection, nonalcoholic fatty liver disease, diabetes mellitus, obesity, and tobacco smoking are additional risk factors for intrahepatic cholangiocarcinoma.

Clinical Findings

Symptoms and Signs

Progressive jaundice is the most common and usually the first sign of obstruction of the extrahepatic biliary system. Pain in the right upper abdomen with radiation into the back is usually present early in the course of gallbladder carcinoma but occurs later in the course of bile duct carcinoma. Anorexia and weight loss are common and may be associated with fever and chills due to cholangitis. Rarely, hematemesis or melena results from erosion of tumor into a blood vessel (hemobilia). Fistula formation between the biliary system and adjacent organs may also occur. The course is usually one of rapid deterioration, with death occurring within a few months.

Physical examination reveals profound jaundice. A palpable gallbladder with obstructive jaundice usually is said to signify malignant disease (Courvoisier law); however, this clinical generalization has been proved to be accurate only about 50% of the time. Hepatomegaly due to hypertrophy of the unobstructed liver lobe is usually present and is associated with liver tenderness.

Ascites may occur with peritoneal implants. Pruritus and skin excoriations are common.

Laboratory Findings

With biliary obstruction, laboratory examination reveals predominantly conjugated hyperbilirubinemia, with total serum bilirubin values ranging from 5 to 30 mg/dL. There is usually concomitant elevation of the alkaline phosphatase and serum cholesterol. AST is normal or minimally elevated. An elevated CA 19-9 level may help distinguish cholangiocarcinoma from a benign biliary stricture (in the absence of cholangitis).

Imaging

Ultrasonography and contrast-enhanced, triple-phase, helical CT may show a gallbladder mass in gallbladder carcinoma and intrahepatic mass or biliary dilation in carcinoma of the bile ducts. CT may also show involved regional lymph nodes and atrophy of a hepatic lobe because of vascular encasement with compensatory hypertrophy of the unaffected lobe. MRI with magnetic resonance cholangiopancreatography (MRCP) and gadolinium enhancement permits visualization of the entire biliary tree and detection of vascular invasion and obviates the need for angiography and, in some cases, direct cholangiography; it has become the imaging procedure of choice but may understage malignant hilar strictures. The sensitivity and image quality can be increased with use of ferumoxide enhancement. In indeterminate cases, PET can detect cholangiocarcinomas as small as 1 cm and lymph node and distant metastases, but false-positive results occur. The most helpful diagnostic studies before surgery are either percutaneous transhepatic or endoscopic retrograde cholangiography with biopsy and cytologic specimens, although false-negative biopsy and cytology results are common. Digital image analysis and fluorescent in situ hybridization of cytologic specimens improve sensitivity. Endoscopic ultrasound (EUS) with FNA of tumors, choledochoscopy, and intraductal ultrasonography may confirm a diagnosis of cholangiocarcinoma in a patient with bile duct stricture and an otherwise indeterminate evaluation.

Treatment

In young and fit patients, curative surgery may be attempted if the tumor is well localized. The 5-year survival rate for carcinoma of the gallbladder invading the lamina propria or muscularis (stage 1, T1a or 1b, N0, M0) is as high as 85% with laparoscopic cholecystectomy but drops to 60%, even with a more extended open resection, if there is perimuscular invasion (T2). The role of radical surgery for T3 and T4 tumors is debatable. If the tumor is unresectable at laparotomy, biliary-enteric bypass (eg, Roux-en-Y hepaticojejunostomy) can be performed.

Carcinoma of the bile ducts is curable by surgery in less than 10% of cases. If resection margins are negative, the 5-year survival rate may be as high as 47% for intrahepatic cholangiocarcinomas, 41% for hilar cholangiocarcinoma, and 37% for distal cholangiocarcinomas, but the perioperative mortality rate may be as high as 10%. Palliation can be achieved by placement of a self-expandable metal stent via an endoscopic or percutaneous transhepatic route. Covered metal stents may be more cost-effective than uncovered metal stents because of a lower risk of stent occlusion, but they are not associated with longer survival. For hilar tumors, there is controversy as to whether unilateral or bilateral stents should be inserted. Plastic stents are less expensive but more prone to occlude than metal ones; they are suitable for patients expected to survive only a few months. Photodynamic therapy in combination with stent placement has been demonstrated to prolong survival when compared with stent placement alone in patients with nonresectable cholangiocarcinoma. Radiotherapy may relieve pain and contribute to biliary decompression. There is limited response to chemotherapy such as with gemcitabine. In general, the prognosis is poor, with few patients surviving for more than 12 months after surgery. Although cholangiocarcinoma is generally considered to be a contraindication to liver transplantation because of rapid tumor recurrence, a 75% 5-year survival rate has been reported in patients with stage I and II cholangiocarcinoma undergoing chemoradiation and exploratory laparotomy followed by liver transplantation.

For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see Chapter 5: Palliative Care & Pain Management).

When to Refer

All patients with carcinoma of the biliary tract should be referred to a specialist.

Carcinoma of the Pancreas & the Periampullary Area

Essentials of Diagnosis

- Obstructive jaundice (may be painless).
- Enlarged gallbladder (may be painful).
- Upper abdominal pain with radiation to back, weight loss, and thrombophlebitis are usually late manifestations.

General Considerations

Carcinomas involving the head of the pancreas, the ampulla of Vater, the distal common bile duct, and the duodenum are considered together, because they are usually indistinguishable clinically; of these, carcinomas of the pancreas constitute over 90%. Carcinoma is the most common neoplasm of the pancreas. About 75% are in the head and 25% in the body and tail of the organ. They comprise 2% of all cancers and 5% of cancer deaths. Risk factors include age, obesity, tobacco use, heavy alcohol use, chronic pancreatitis, prior abdominal radiation, and family history. New-onset diabetes mellitus after age 45 years occasionally heralds the onset of early pancreatic cancer. About 7–8% of patients with pancreatic cancer have a family history of pancreatic cancer in a first-degree relative, compared with 0.6% of control subjects. Point mutations in codon 12 of the K-*ras* oncogene are found in 70–100%, inactivation of the tumor suppressor genes *INK4A* on chromosome 9, *TP53* on chromosome 17, and *MADH4* on chromosome 18 is found in 95%, 75%, and 55% of pancreatic cancers, respectively, and mutation of the palladin gene is reported to be common. Pancreatic cancer can also occur as part of several hereditary syndromes, including familial breast cancer (carriers of *BRCA-2* have a 7% lifetime risk of pancreatic cancer), hereditary pancreatitis (*PSS1* mutation), familial cutaneous malignant melanoma (*CDKN2A* mutation), Peutz–Jeghers syndrome, ataxia-telangiectasia, and hereditary nonpolyposis colorectal cancer. Polymorphisms of the genes for methylene tetrahydrofolate reductase and thymidylate synthase have been reported to be associated with pancreatic cancer. Neuroendocrine tumors account for 1–2% of pancreatic neoplasms and may be functional (producing gastrin, insulin, glucagon, vasoactive intestinal peptide, somatostatin, growth hormone–releasing hormone, adrenocorticotropic hormone, and others) or nonfunctional. Plasma chronogranin A levels are elevated in 88–100% of affected patients. Cystic neoplasms account for only 1% of pancreatic cancers, but they are important because they are often mistaken for pseudocysts. A cystic neoplasm should be suspected when a cystic lesion in the pancreas is found in the absence of a history of pancreatitis. At least 15% of all pancreatic cysts are neoplasms. Whereas serous cystadenomas (which account for 32–39% of cystic pancreatic neoplasms and also occur in patients with von Hippel–Lindau disease) are benign, mucinous cystic neoplasms (defined by the presence of ovarian stroma) (10–45%), intraductal papillary mucinous neoplasms (21–33%), solid pseudopapillary neoplasms (< 5%), and cystic islet cell tumors (3–5%) may be malignant, although their prognoses are better than the prognosis of adenocarcinoma of the pancreas, unless the neoplasm is locally advanced.

Clinical Findings

Symptoms and Signs

Pain is present in over 70% of cases and is often vague, diffuse, and located in the epigastrium or left upper quadrant when the lesion is in the tail. Radiation of pain into the back is common and sometimes predominates. Sitting up and leaning forward may afford some relief, and this usually indicates that the lesion has spread beyond the pancreas and is inoperable. Diarrhea, perhaps due to maldigestion, is an occasional early symptom. Migratory thrombophlebitis is a rare sign. Weight loss is a common but late finding and may be associated with depression. Occasionally a patient presents with acute pancreatitis in the absence of an alternative cause. Jaundice is usually due to biliary obstruction by a cancer in the pancreatic head. A palpable gallbladder is also indicative of obstruction by neoplasm (Courvoisier law), but there are frequent exceptions. A hard, fixed, occasionally tender mass may be present. In advanced cases, a hard periumbilical (Sister Joseph's) nodule may be palpable.

Laboratory Findings

There may be mild anemia. Glycosuria, hyperglycemia, and impaired glucose tolerance or true diabetes mellitus are found in 10–20% of cases. The serum amylase or lipase level is occasionally elevated. Liver biochemical tests may suggest obstructive jaundice. Steatorrhea in the absence of jaundice is uncommon. Occult blood in the stool is suggestive of carcinoma of the ampulla of Vater (the combination of biliary obstruction and bleeding may give the stools a distinctive silver appearance). CA 19-9, with a sensitivity of 70% and a specificity of 87%, has not proved sensitive enough for early detection of pancreatic cancer; increased values are also found in acute and chronic pancreatitis and cholangitis.

Imaging

With carcinoma of the head of the pancreas, an upper gastrointestinal series may show a widening of the duodenal loop, mucosal abnormalities in the duodenum ranging from edema to invasion or ulceration, spasm, or compression. Ultrasound is not reliable because of interference by intestinal gas. Multiphase thin-cut helical CT scanning is generally the initial diagnostic procedure and detects a mass in over 80% of cases. CT scanning identifies metastases, delineates the extent of the tumor, and allows for percutaneous FNA for cytologic studies and tumor markers. MRI is an alternative to CT scanning. Preliminary experience suggests that PET is a sensitive technique for detecting pancreatic cancer and metastases. Selective celiac and superior mesenteric arteriography may demonstrate vessel invasion by tumor, a finding that would interdict attempts at surgical resection, but it is less widely used since the advent of multiphase helical CT. Endoscopic ultrasonography is more sensitive than CT scanning for detecting pancreatic cancer and equivalent to CT scanning for determining nodal involvement and resectability. A normal EUS excludes pancreatic cancer.

Endoscopic ultrasonography may also be used to guide FNA for tissue diagnosis and tumor markers. Endoscopic retrograde cholangiopancreatography (ERCP) may clarify an ambiguous CT scan or MRI study by delineating the pancreatic duct system or confirming an ampullary or biliary neoplasm. MRCP appears to be at least as sensitive as ERCP in diagnosing pancreatic cancer. In some centers, pancreatoscopy or intraductal ultrasonography can be used to evaluate filling defects in the pancreatic duct and assess resectability of intraductal papillary mucinous tumors. With obstruction of the splenic vein, splenomegaly or gastric varices are present, the latter delineated by endoscopy, endoscopic ultrasonography, or angiography.

Cystic neoplasms can be distinguished by their appearance on CT, endoscopic ultrasonography, and ERCP and features of the cyst fluid on gross and cytologic analysis. For example, serious cystadenomas may have a central scar or honeycomb appearance; mucinous cystadenomas are unilocular or multilocular and contain mucin-rich fluid with high carcinoembryonic antigen levels (> 200 ng/mL); and intraductal papillary mucinous neoplasms are associated with a dilated pancreatic duct and extrusion of gelatinous material from the ampulla.

Staging of pancreatic cancer by the TNM classification includes the following definitions: Tis: carcinoma in situ; T1: tumor limited to the pancreas, 2 cm or less in greatest dimension; T2: tumor limited to the pancreas, more than 2 cm in greatest dimension; T3: tumor extends beyond the pancreas but without involvement of the celiac axis or the superior mesenteric artery; T4, tumor involves the celiac axis or the superior mesenteric artery (unresectable primary tumor).

Treatment

Abdominal exploration is usually necessary when cytologic diagnosis cannot be made or if resection is to be attempted, which includes about 30% of patients. In a patient with a localized mass in the head of the pancreas and without jaundice, laparoscopy may detect tiny peritoneal or liver metastases and thereby avoid resection in 4–13% of patients. Radical pancreaticoduodenal (Whipple) resection is indicated for lesions strictly limited to the head of the pancreas, periampullary area, and duodenum (T1, N0, M0). Five-year survival rates are 20–25% in this group and as high as 40% in those with negative resection margins and without lymph node involvement. Preoperative endoscopic decompression of an obstructed bile duct is often achieved with a plastic stent or short metal stent but does not reduce operative mortality or morbidity. The best surgical results are achieved at centers that specialize in the multidisciplinary treatment of pancreatic cancer. Adjuvant or neoadjuvant chemotherapy with gemcitabine and fluorouracil, possibly combined with irradiation, appears to be of benefit (Table 39–4). When resection is not feasible, endoscopic stenting of the bile duct is performed to relieve jaundice. A plastic stent is generally placed if the patient's anticipated survival is less than 6 months (or surgery is planned). A metal stent is preferred when anticipated survival is 6 months or greater. Surgical biliary bypass may be considered in patients expected to survive at least 6 months. Surgical duodenal bypass may be considered in patients in whom duodenal obstruction is expected to develop later; alternatively, endoscopic placement of a self-expandable duodenal stent may be feasible. Chemoradiation may be used for palliation of unresectable cancer confined to the pancreas. Chemotherapy has been disappointing in metastatic pancreatic cancer, although improved response rates have been reported with gemcitabine. Novel small molecules (eg, erlotinib), capecitabine (an oral fluoropyrimidine), nucleoside cytidine analogues, and topoisomerase inhibitors are under study. Celiac plexus nerve block or thoracoscopic splanchnicectomy may improve pain control. Photodynamic therapy is under study.

Table 39–4. Treatment choices for cancers responsive to systemic agents.

Diagnosis	Current Treatment of Choice	Other Treatments
Acute lymphocytic leukemia (ALL)	**Induction combination chemotherapy:** Vincristine, prednisone, daunorubicin, asparaginase, intrathecal methotrexate	Imatinib mesylate (Ph positive ALL), autologous or allogeneic transplantation for high risk or at relapse
	Consolidation combination chemotherapy: Cyclophosphamide, vincristine, doxorubicin, dexamethasone (hyper-CVAD) alternated with cytarabine, methotrexate	
	Maintenance: Methotrexate,6-mercaptopurine	
Acute myelogenous leukemia (AML)	**Combination chemotherapy:** Cytarabine plus daunorubin or idarubicin	Gemtuzumab ozogamicin, prednisone, doxorubicin

Chronic myelocytic leukemia (CML)	Imatinib mesylate	Dasatinib, nilotinib, allogeneic bone marrow transplantation, hydroxyurea, interferon- , cytarabine, busulfan
Chronic lymphocytic leukemia (CLL)	**Combination chemotherapy:** Fludarabine, cyclophosphamide, rituximab (FCR); Fludarabine; or Chlorambucil	Alemtuzumab, bendamustine, pentostatin, cladribine, cyclophosphamide, vincristine, doxorubicin, prednisone
Hairy cell leukemia	Cladribine (2-chlorodeoxyadenosine)	Pentostatin, interferon-
Hodgkin disease (stages III and IV)	**Combination chemotherapy:** Doxorubicin, bleomycin, vinblastine, dacarbazine (ABVD); Doxorubicin, vinblastine,	Gemcitabine, vinorelbine, ifosfamide, cyclophosphamide, procarbazine, transplantation

	mechlorethamine, etoposide, vincristine, bleomycin, prednisone (Stanford V)	for relapse
Non-Hodgkin lymphoma (intermediate and high grade)	**Combination chemotherapy:** Cyclophosphamide, doxorubicin, vincristine, prednisone, rituximab (CHOP-R)	**Combination chemotherapy second line:** Dexamethasone, cisplatin, cytarabine (DHAP)Etoposide, methylprednisolone, cytarabine, cisplatin (ESHAP) Ifosfamide, carboplatin, etoposide (ICE)Mesna, ifosfamide, mitoxantrone, etoposide (MINE); transplantation for high risk or

		first relapse
Non-Hodgkin lymphoma (low grade)	**Combination chemotherapy:** Fludarabine, cyclophosphamide, rituximab (FCR) Cyclophosphamide, vincristine, doxorubicin, prednisone, rituximab (CHOP-R), or Cyclophosphamide, vincristine, prednisone, rituximab (CVP-R) or Chlorambucil	^{131}I tositumomab, ^{90}Y ibritumomab tiuxetan, bendamustine, autologous or allogeneic transplantation
Multiple myeloma	**Combination chemotherapy (transplant candidates):** Bortezomib, dexamethasone, thalidomide or lenalidomide Dexamethasone, thalidomide or lenalidomideDexamethasone followed by autologous or	Bortezomib, lenalidomide, thalidomide, dexamethasone, cyclophosphamide

	miniallogeneic stem cell transplantation	
	Combination chemotherapy (non-transplant candidates): Melphalan, prednisone, bortezomib Melphalan, prednisone	
Waldenstrom macroglobulinemia	**Combination therapy:** Fludarabine, cyclophosphamide, rituximab (FCR), with or without plasmapheresis	Cladribine, thalidomide, bortezomib, chlorambucil, autologous bone marrow transplantation, prednisone
Polycythemia vera	Phlebotomy, hydroxyurea	Anagrelide, radiophosphorus ^{32}P, interferon- , busulfan, chlorambucil, cyclophosphamide
Non-small cell	**Combination**	Docetaxel,

lung cancer	**chemotherapy:** Cisplatin, vinorelbine Cisplatin, gemcitabineCisplatin, etoposidePaclitaxel, carboplatin; all regimens with or without bevacizumab	vinorelbine, pemetrexed, erlotinib, cetuximab
Small cell lung cancer	**Combination chemotherapy:** Cisplatin, etoposide	Irinotecan, cyclophosphamide, doxorubicin, vincristine, topotecan
Mesothelioma	**Combination chemotherapy:** Cisplatin, pemetrexed	Doxorubicin
Head and neck cancer	**Combination chemotherapy:** Cisplatin, fluorouracilPaclitaxel, carboplatinDocetaxel, cisplatin, fluorouracil Cisplatin or cetuximab with radiation therapy	Hydroxyurea, bleomycin, methotrexate, cetuximab
Esophageal cancer	**Combination chemotherapy:**	Paclitaxel, irinotecan,

	Cisplatin, fluorouracil	oxaliplatin, capecitabine, docetaxel, epirubicin
Uterine cancer	**Combination chemotherapy:** Cisplatin, doxorubicin, paclitaxel Cisplatin, doxorubicin Carboplatin, paclitaxel	Fluorouracil
Ovarian cancer	**Combination chemotherapy:** Paclitaxel, carboplatin Intraperitoneal cisplatin, paclitaxelDocetaxel, carboplatinPaclitaxel, cisplatin	Gemcitabine, liposomal doxorubicin, topotecan, cyclophosphamide, etoposide, docetaxel
Cervical cancer	**With radiation:** Cisplatin	Docetaxel, ifosfamide, vinorelbine, irinotecan, epirubicin, mitomycin, fluorouracil
	Combination chemotherapy: Cisplatin, paclitaxelCisplatin, topotecan Carboplatin, paclitaxelCisplatin, gemcitabine	

Breast cancer	**Adjuvant endocrine therapy:** Premenopausal: Tamoxifen Postmenopausal: Aromatase inhibitors (anastrozole, letrozol, exemestane)	Megestrol, aminoglutethimide, capecitabine, mitoxantrone, cisplatin, etoposide, vinblastine, fluorouracil, ixabepilone, gemcitabine
	Adjuvant chemotherapy (without trastuzumab): Doxorubicin, cyclophosphamide, docetaxel Doxorubicin, cyclophosphamide, paclitaxelDocetaxel, cyclophosphamideDoxorubicin, cyclophosphamide	
	Adjuvant chemotherapy (with trastuzumab): Doxorubicin, cyclophosphamide, paclitaxel, trastuzumab Docetaxel, carboplatin, trastuzumab	

Choriocarcinoma (trophoblastic neoplasms)	***Single agents:*** Methotrexate or dactinomycin for low risk disease **Combination chemotherapy:** Etoposide/methotrexate, dactinomycin, cyclophosphamide, vincristine (EMA-CO) for high-risk disease	Vinblastine, cisplatin, mercaptopurine, chlorambucil, doxorubicin
Testicular cancer	**Combination chemotherapy:** Bleomycin, etoposide, cisplatin (BEP)Cisplatin, etoposide (EP)	Vinblastine, ifosfamide, paclitaxel, mesna
Kidney cancer	Sunitinib, temsirolimus, bevacizumab, sorafenib, interleukin-2	Interferon- , vinblastine, capecitabine, fluorouracil
Bladder cancer	**Combination chemotherapy:** Gemcitabine, cisplatin	Carboplatin, paclitaxel, docetaxel, fluorouracil, pemetrexed, methotrexate

Prostate cancer	Luteinizing hormone-releasing agonist (leuprolide, goserelin, triptorelin) plus an antiandrogen (flutamide, bicalutamide, nilutamide)	Ketoconazole, docetaxel, mitoxantrone, estramustine, prednisone
Brain cancer (anaplastic astrocytoma and glioblastoma multiforme	Temozolomide	Bevacizumab, irinotecan, procarbazine, carmustine, lomustine
Neuroblastoma	**Combination chemotherapy:** Cyclophosphamide, doxorubicin, cisplatin, etoposide	Vincristine, topetecan, irinotecan, ifosfamide, carboplatin, 13-cis-retinoic acid, ^{131}I-MIBG, autologous or allogeneic transplantation
Thyroid cancer	Radioiodine (^{131}I), sorafenib	Doxorubicin, dacarbazine

Adrenal cancer	Mitotane	Doxorubicin, etoposide, cisplatin
Stomach cancer	**Combination chemotherapy:** Epirubicin, cisplatin, fluorouracilDocetaxel, cisplatin, fluorouracil Fluorouracil, leucovorin, oxaliplatin	Capecitabine, sorafenib
Pancreatic cancer	**Combination chemotherapy:** Gemcitabine, cisplatin; Gemcitabine, erlotinib; Gemcitabine	Capecitabine, fluorouracil, oxaliplatin
Colon cancer	**Combination chemotherapy:** Fluorouracil, leucovorin, oxaliplatin (FOLFOX6) Capecitabine, oxaliplatin (CapeOx)Fluorouracil, leucovorin, irinotecan (FOLFIRI); each regimen with or without bevacizumab	Cetuximab, irinotecan, panitumumab

Rectal cancer	**Chemotherapy with radiation:** Fluorouracil; for advanced disease same regimens used with colon cancer	Cetuximab, irinotecan, panitumumab
Anal cancer	**Combination chemotherapy with radiation:** Fluorouracil, mitomycin	Cisplatin
Carcinoid	**Combination chemotherapy:** Streptozocin, fluorouracil;Cisplatin, etoposide	Doxorubicin, dacarbazine, octreotide, interferon-
Insulinoma	Interferon, streptozocin	Doxorubicin, fluorouracil, mitomycin
Osteogenic sarcoma	**Combination chemotherapy with two of these agents:** Doxorubicin, cisplatin, ifosfamide, high-dose methotrexate	Cyclophospha mide, dacarbazine
Soft tissue sarcomas	**Combination chemotherapy:** Doxorubicin,	Liposomal doxorubicin, methotrexate,

	dacarbazine (AD) Doxorubicin, ifosfamide, mesna (AIM)Mesna, doxorubicin, ifosfamide, dacarbazine (MAID)	gemcitabine, docetaxel
Melanoma	Dacarbazine, temozolomide, high-dose interleukin-2	Paclitaxel, cisplatin, carboplatin, interferon- , vinblastine
Hepatocellular cancer	Sorafenib	Doxorubicin
Kaposi sarcoma	Liposomal doxorubicin, liposomal daunorubicin	Paclitaxel, vinblastine, vincristine, etoposide, doxorubicin

Surgical resection is the treatment of choice for neuroendocrine tumors, when feasible. Metastatic disease may be controlled with long-acting somatostatin analogs, interferon, peptide-receptor radionuclide therapy, and chemoembolization. There is a growing consensus that asymptomatic incidental pancreatic cysts of 2 cm or less are at low risk of invasive carcinoma and may be followed by imaging tests at 6-month intervals, with surgery performed if a cyst enlarges or exceeds 2.5 cm.

Surgical resection is indicated for mucinous cystic neoplasms, symptomatic serous cystadenomas, and cystic tumors larger than 2 cm in diameter that remain undefined after helical CT, EUS, and diagnostic aspiration. All intraductal papillary mucinous neoplasms of the main pancreatic duct should be resected, but those of branch ducts may be followed with serial imaging if they are asymptomatic and exhibit benign features (eg, diameter < 3 cm, absence of nodules or thick walls); most of the latter remain stable on follow-up, but the risk of pancreatic ductal carcinoma and of nonpancreatic cancers may also be increased in this group of patients. In the absence of locally advanced disease, survival is higher for malignant cystic neoplasms than for adenocarcinoma. Endoscopic resection or ablation, with temporary placement of a pancreatic duct stent, may be feasible for ampullary adenomas, but patients must be followed for recurrence.

Prognosis

Carcinoma of the pancreas, especially in the body or tail, has a poor prognosis. Reported 5-year survival rates range from 2% to 5%. Lesions of the ampulla have a better prognosis, with reported 5-year survival rates of 20–40% after resection; jaundice and lymph node involvement are adverse prognostic factors. In carefully selected patients, resection of cancer of the pancreatic head is feasible and results in reasonable survival. In persons with a strong family history of pancreatic cancer, screening with helical CT and endoscopic ultrasonography should be considered beginning 10 years before the age at which pancreatic cancer was diagnosed in a family member.

For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see Chapter 5: Palliative Care & Pain Management).

When to Refer

All patients with carcinoma involving the pancreas and the periampullary area should be referred to a specialist.

When to Admit

Patients who require surgery and other interventions should be hospitalized.

Esophageal Cancer

Kenneth R. McQuaid, MD

Essentials of Diagnosis

- Progressive solid food dysphagia.
- Weight loss common.
- Endoscopy with biopsy establishes diagnosis.

General Considerations

Esophageal cancer usually develops in persons between 50 and 70 years of age. The overall ratio of men to women is 3:1. There are two histologic types: squamous cell carcinoma and adenocarcinoma. In the United States, **squamous cell cancer** is much more common in blacks than in whites. Chronic alcohol and tobacco use are strongly associated with an increased risk of squamous cell carcinoma. The risk of squamous cell cancer is also increased in patients with tylosis (a rare disease transmitted by autosomal dominant inheritance and manifested by hyperkeratosis of the palms and soles), achalasia, caustic-induced esophageal stricture, and other head and neck cancers. Squamous cell cancer has a high incidence in certain regions of China and Southeast Asia. Half of all cases occur in the distal third of the esophagus. **Adenocarcinoma** is more common in whites. It is increasing dramatically in incidence and now is as common as squamous carcinoma. The majority of adenocarcinomas develop as a complication of Barrett metaplasia due to chronic gastroesophageal reflux. Thus, most adenocarcinomas arise in the distal third of the esophagus. Obesity also is strongly associated with adenocarcinoma, even after controlling for gastroesophageal reflux; however, no causal relationship has been convincingly shown.

Clinical Findings

Symptoms and Signs

Most patients with esophageal cancer present with advanced, incurable disease. Over 90% have solid food dysphagia, which progresses over weeks to months. Odynophagia is sometimes present. Significant weight loss is common. Local tumor extension into the tracheobronchial tree may result in a tracheoesophageal fistula, characterized by coughing on swallowing or pneumonia. Chest or back pain suggests mediastinal extension. Recurrent laryngeal involvement may produce hoarseness. Physical examination is often unrevealing. The presence of supraclavicular or cervical lymphadenopathy or of hepatomegaly implies metastatic disease.

Laboratory Findings

Laboratory findings are nonspecific. Anemia related to chronic disease or occult blood loss is common. Elevated aminotransferase or alkaline phosphatase concentrations suggest hepatic or bony metastases. Hypoalbuminemia may result from malnutrition.

Imaging

Chest radiographs may show adenopathy, a widened mediastinum, pulmonary or bony metastases, or signs of tracheoesophageal fistula such as pneumonia. A barium esophagogram may be the first study obtained to evaluate dysphagia. The appearance of a polypoid, infiltrative, or ulcerative lesion is suggestive of carcinoma and requires endoscopic evaluation. However, even lesions believed to be benign by radiography warrant endoscopic evaluation.

Upper Endoscopy

Endoscopy with biopsy establishes the diagnosis of esophageal carcinoma with a high degree of reliability. In some cases, significant submucosal spread of the tumor may yield nondiagnostic mucosal biopsies. Repeated biopsy may be necessary.

Staging

After confirmation of the diagnosis of esophageal carcinoma, the stage of the disease should be determined since doing so influences the choice of therapy. Patients should undergo evaluation with CT of the chest and abdomen to look for evidence of pulmonary or hepatic metastases, lymphadenopathy, and local tumor extension. If there is no evidence of distant metastases or extensive local spread on CT, endoscopic ultrasonography with guided FNA biopsy of lymph nodes should be performed, which is superior to CT in demonstrating the level of local mediastinal extension and local lymph node involvement. PET with fluorodeoxyglucose or integrated PET-CT imaging is more sensitive (and expensive) than CT for detection of distant metastasis. It is increasingly used to look for regional or distant spread in patients thought to have localized disease after other diagnostic studies. Bronchoscopy is sometimes required in proximal esophageal cancer to exclude tracheobronchial extension. Apart from distant metastasis (M1b), the two most important predictors of poor survival are adjacent mediastinal spread (T4) and lymph node involvement. Whereas cure may be achieved in patients with regional lymph node involvement (stages IIB and III), involvement of nodes outside the chest (M1a) is indicative of metastatic disease (stage IV) that is incurable.

Differential Diagnosis

Esophageal carcinoma must be distinguished from other causes of progressive dysphagia, including peptic stricture, achalasia, and adenocarcinoma of the gastric cardia with esophageal involvement. Benign-appearing peptic strictures should be biopsied at presentation to exclude occult malignancy.

Treatment

The approach to esophageal cancer depends on the tumor stage, patient preference and functional status, and the expertise of the attending surgeons, oncologists, gastroenterologists, and radiotherapists. There is no consensus about the optimal treatment approach. It is helpful, however, to classify patients into two general categories.

Therapy for "Curable" Disease

Superficial esophageal cancers confined to the epithelium (high-grade dysplasia or carcinoma in situ [Tis]), lamina propria (T1a), or submucosal (T1b) are increasingly recognized in endoscopic screening and surveillance programs. Esophagectomy achieves high cure rates but is associated with mortality (2%) and morbidity. If performed by experienced physicians, endoscopic mucosal resection of superficial cancers (especially Tis and T1a) achieves equivalent long-term survival with less morbidity. For a full discussion of management options in superficial adenocarcinoma, see the section on Barrett Esophagus in Chapter 15: Gastrointestinal Disorders. The management of other invasive but potentially "curable" esophageal cancers (stage I, II, or IIIA) is controversial and depends on institutional experience.

Surgery with or without neoadjuvant chemoradiation therapy

There is debate over the optimal surgical approach. The procedure with the lowest morbidity is transhiatal esophagectomy with anastomosis of the stomach to the cervical esophagus; however, this approach does not involve sampling or removal of mediastinal lymph nodes. Alternatively, surgeons may perform en bloc transthoracic excision of the esophagus with extended dissection of lymph nodes in the mediastinum and upper abdomen. In a randomized controlled trial comparing these two approaches, en bloc resection was associated with higher perioperative morbidity but a nonsignificant trend toward improved 5-year survival (39% vs 27%). Transhiatal resection may be more appropriate for patients who are elderly or have comorbid illness, and en bloc resection more appropriate in younger or healthier patients with a better prognosis.

Patients without regional lymph node spread (stage I and stage IIA) have high cure rates with surgery alone and require no other radiation or chemotherapy. If regional lymph node metastases have occurred (stage IIB and stage IIIA), the rate of cure with surgery alone is reduced to less than 20%. Meta-analysis of trials comparing neoadjuvant therapy followed by surgery with surgery alone suggests a

13% absolute improvement in 2-year survival with combined therapy. Therefore, in many centers, preoperative (neoadjuvant) chemoradiation therapy is recommended. The most commonly used chemotherapeutic agents are cisplatin and 5-fluorouracil (5-FU), although the optimal regimen is unclear. Furthermore, the superiority of this combined approach compared with surgery alone, or surgery with postoperative adjuvant chemotherapy is unproven.

Chemotherapy plus radiation therapy without surgery

Combined treatment with chemotherapy and radiation therapy is superior to radiation therapy alone and has achieved long-term survival rates in up to 25% of patients. In two randomized trials, there was no difference in long-term survival between patients treated with chemoradiation therapy alone versus chemoradiation therapy followed by surgery, although combination therapy achieves superior control of mediastinal disease with a reduced need for subsequent palliative therapies. Chemoradiation therapy alone should be considered in patients with localized disease (stage II or IIIA) who are poor surgical candidates due to serious medical illness or poor functional status (Eastern Cooperative Oncology Group score > 2).

Therapy for Incurable Disease

More than half of patients have either locally extensive tumor spread (T4) that is unresectable or distant metastases (M1) ie, stage IIIB and stage IV tumors. Surgery is not warranted in these patients. Since prolonged survival can be achieved in few patients, the primary goal is to provide relief from dysphagia and pain, optimize quality of life, and minimize treatment side effects. The optimal palliative approach depends on the presence or absence of metastatic disease, patient's expected survival, patient preference, and local institutional experience. Many patients with advanced disease may prefer concerted efforts at pain relief and care directed at symptom management (see Chapter 5: Palliative Care & Pain Management).

Radiation therapy, chemotherapy, and combined therapy

Combined radiation therapy and chemotherapy (5-FU and cisplatin) may achieve palliation in two-thirds of patients but is associated with significant side effects. It should be considered for patients with locally advanced tumors without distant metastases (stage IIIB) who have good functional status, no significant medical problems, in whom prolonged survival may be achieved. Improvement in dysphagia occurs within 2–4 weeks in almost 90% of patients.

Combination chemotherapy may be considered in patients with metastatic disease who still have good functional status and expected survival of several months. Although there is no consensus on optimal therapy, three drug combinations are commonly used: (1) epirubicin or a taxane (docetaxel or paclitaxel), (2) cisplatin or oxaliplatin, and (3) a fluoropyrimidine (5-FU or capecitabine). For patients with poor functional status, single-agent therapy with a fluoropyrimidine, a taxane, or irinotecan may be used. The role of biologic agents (anti-EGFR, anti-VEGF, kinase inhibitors) requires further study.

Radiation therapy alone may afford short-term relief of pain and dysphagia and may be suitable for patients with poor functional status or underlying medical problems. Because it takes up to 6 weeks to administer and may be complicated by temporary worsening of dysphagia and odynophagia, local antitumor therapies may be preferred.

Local antitumor therapy

Patients with advanced esophageal cancer often have a poor functional and nutritional status with an average survival of less than 12 weeks from diagnosis. Radiation or chemoradiation is poorly tolerated. Rapid palliation of dysphagia may be achieved by peroral placement of permanent expandable wire stents, application of endoscopic laser therapy, or photodynamic therapy. Although dysphagia and quality of life are improved significantly, patients can seldom eat normally. The choice of treatment depends on available expertise and equipment. Stents are most commonly used because of their relative ease of placement. Complications of stents occur in 20–40% and include perforation, migration, and tumor ingrowth.

Prognosis

The overall 5-year survival rate of esophageal carcinoma is less than 20%. For those patients whose disease progresses despite chemotherapy, meticulous efforts at palliative care are essential (see Chapter 5: Palliative Care & Pain Management).

When to Refer

- Patients should be referred to gastroenterologist for evaluation and staging (endoscopy with biopsy, EUS) and palliative endoscopic antitumor therapy (stent).
- Patients with curable and resectable disease (stage IIB or IIIA) and those with locally advanced or metastatic disease should be referred to an oncologist for consideration of neoadjuvant chemotherapy or consideration of chemoradiotherapy or palliative chemotherapy, respectively.

When to Admit

Patients with high-grade esophageal obstruction with inability to manage oral secretions should be admitted.

Gastric Adenocarcinoma

Essentials of Diagnosis

- Dyspeptic symptoms with weight loss in patients over age 40 years.
- Iron deficiency anemia: occult blood in stools.
- Abnormality detected on upper gastrointestinal series or endoscopy.

General Considerations

Gastric adenocarcinoma remains the second most common cause of cancer death worldwide. Its incidence however has declined rapidly over the last 70 years, especially in western countries, which may be attributable to changes in diet (more fruits and vegetables), food refrigeration (allowing more fresh foods and reduced salted, smoked, and preserved foods), reduced toxic environmental exposures, and a decline in *Helicobacter pylori*. The incidence of gastric cancer remains high (70/100,000) in Japan and many developing regions, including eastern Asia, Eastern Europe, Chile, Colombia, and Central America. In the United States, there were an estimated 21,500 new cases and 10,800 deaths in 2008. The incidence is higher in Latinos, African Americans, and Asian Americans.

There are two main histologic variants of gastric cancer: "intestinal-type" (which resembles intestinal cancers in forming glandular structures) and "diffuse" (which is poorly differentiated, has signet-ring cells, and lacks glandular formation). Although both types are declining in incidence, intestinal-type has had the most dramatic reduction. Intestinal-type is still more common (70–80%), occurs twice as often in men as women, primarily affects older people (mean age 63 years), and is more strongly associated with environmental factors. It is believed to arise through a gradual, multi-step progression from inflammation (most commonly due to *H pylori*), to atrophic gastritis, to intestinal metaplasia, and finally dysplasia or cancer. Chronic *H pylori* gastritis is the strong risk factor for gastric carcinoma, increasing the relative risk 3.5- to 20-fold. It is estimated that 60–90% of cases of gastric carcinomas may be attributable to *H pylori*. Because of its unproven efficacy and cost-effectiveness, screening for *H pylori* infection and treating it to prevent gastric cancer is not recommended for asymptomatic adults in the general population but may be considered in patients who have immigrated from regions with a high incidence of gastric cancer or who have a family history of gastric cancer. Other risk factors for intestinal-type gastric cancer include pernicious anemia, a history of partial gastric resection more than 15 years previously, smoking, and diets that are high in nitrates or salt and low in vitamin C.

Diffuse gastric cancer accounts for 20–30% of gastric cancer. In contrast to intestinal-type cancer, it affects men and women equally, occurs more commonly in young people, is not as strongly related to *H pylori* infection, has a worse prognosis, and has not declined in incidence. Most diffuse gastric cancers are attributable to acquired or hereditary mutations in the genes regulating the E-cadherin cell adhesion protein. Familial diffuse gastric cancer accounts for 1–3% of gastric cancers. The cancer may arise at a young age, is often multifocal and infiltrating, and carries a poor prognosis. Many of these families have a germline mutation of E-cadherin *CDH1*, which is inherited in an autosomal dominant pattern and carries a greater than 60% lifetime risk of gastric cancer.

Most gastric cancers arise in the body and antrum. These may occur in a variety of morphologic types: (1) polypoid or fungating intraluminal masses; (2) ulcerating masses; (3) diffusely spreading (linitis plastica), in which the tumor spreads through the submucosa, resulting in a rigid, atonic stomach with thickened folds (prognosis dismal); and (4) superficially spreading or "early" gastric cancer—confined to the mucosa or submucosa (with or without lymph node metastases) and associated with an excellent prognosis.

In contrast to the dramatic decline in cancers of the distal stomach, a rise in incidence of tumors of the gastric cardia has been noted. These tumors have demographic and pathologic features that resemble Barrett-associated esophageal adenocarcinomas (see Esophageal Cancer).

Clinical Findings

Symptoms and Signs

Gastric carcinoma is generally asymptomatic until the disease is quite advanced. Symptoms are nonspecific and are determined in part by the location of the tumor. Dyspepsia, vague epigastric pain, anorexia, early satiety, and weight loss are the presenting symptoms in most patients. Patients may derive initial symptomatic relief from over-the-counter remedies, further delaying diagnosis. Ulcerating lesions can lead to acute gastrointestinal bleeding with hematemesis or melena. Pyloric obstruction results in postprandial vomiting. Lower esophageal obstruction causes progressive dysphagia. Physical examination is rarely helpful. A gastric mass is palpated in less than 20% of patients. Signs of metastatic spread include a left supraclavicular lymph node (Virchow node), an umbilical nodule (Sister Mary Joseph nodule), a rigid rectal shelf (Blumer shelf), and ovarian metastases (Krukenberg tumor). Guaiac-positive stools may be detectable.

Laboratory Findings

Iron deficiency anemia due to chronic blood loss or anemia of chronic disease is common. Liver function test abnormalities may be present if there is metastatic liver spread. Other tumor markers are of no value.

Endoscopy

Upper endoscopy should be obtained in all patients over age 55 years with new onset of epigastric symptoms (dyspepsia) and in anyone with dyspepsia that is persistent or fails to respond to a short trial of antisecretory therapy. Endoscopy with biopsies of suspicious lesions is highly sensitive for detecting gastric carcinoma. It can be difficult to obtain adequate biopsy specimens in linitis plastica lesions. Because of the high incidence of gastric carcinoma in Japan, screening upper endoscopy is performed to detect early gastric carcinoma. Approximately 40% of tumors detected by screening are early, with a 5-year survival rate of almost 90%. Screening programs are not recommended in the United States.

Imaging

A barium upper gastrointestinal series is an acceptable alternative when endoscopy is not readily available but may not detect small or superficial lesions and cannot reliably distinguish benign from malignant ulcerations. Any abnormalities detected with this procedure require endoscopic confirmation.

Once a gastric cancer is diagnosed, preoperative evaluation with abdominal and chest CT and EUS is indicated to delineate the local extent of the primary tumor as well as nodal or distant metastases. PET or combined PET-CT imaging may be more sensitive than

CT for detection of distant metastasis. EUS imaging is superior to CT in determining the depth of tumor penetration and is useful for evaluation of early gastric cancers that may be removed by endoscopic mucosal resection.

Staging

Staging is defined according to the TNM system, in which T1 tumors invade the lamina propria (T1a) or submucosa (T1b), T2 invade the muscularis propria, T3 penetrate the serosa, and T4 invade adjacent structures. Lymph nodes are graded as N0 if there is no involvement, and N1, N2, or N3 if there are is involvement of 1–6, 7–15, or more than 15 regional nodes. M1 signifies the presence of metastatic disease.

Differential Diagnosis

Ulcerating gastric adenocarcinomas are distinguished from benign gastric ulcers by biopsies. Approximately 3% of gastric ulcers initially believed to be benign later prove to be malignant. To exclude malignancy, all gastric ulcers identified at endoscopy should be biopsied. Ulcers that are suspicious for malignancy to the endoscopist or that have atypia or dysplasia on histologic examination warrant repeat endoscopy in 2–3 months to verify healing and exclude malignancy. Nonhealing ulcers should be considered for resection. Infiltrative carcinoma with thickened gastric folds must be distinguished from lymphoma and other hypertrophic gastropathies.

Treatment

Curative Surgical Resection

After preoperative staging, about two-thirds of patients will be found to have localized disease (ie, stages I–III). In Japan and in specialized centers in the United States, endoscopic mucosal resection is performed in selected patients with small (< 1–2 cm), early (intramucosal or T1aN0) gastric cancers after careful staging with EUS. For all other patients, surgical resection is the only therapy with curative potential. At surgery, approximately 25% of these patients will be found to have locally unresectable tumors or peritoneal, hepatic, or distant lymph node metastases for which "curative" surgical resection is not warranted (see below). The remaining patients with confirmed localized disease should undergo radical surgical resection with curative intent. For adenocarcinoma localized to the distal two-thirds of the stomach, a subtotal distal gastrectomy should be performed. For proximal gastric cancer or diffusely infiltrating disease, total gastrectomy is necessary. Although lymph node dissection should be performed for curative resections, there has been ongoing debate about whether an extended (perigastric; D1), regional (D2), or distant (porta hepatic and periaortic; D3) lymph node dissection is needed. A 2008 large Japanese trial found no difference in survival between patients treated with D2 and D3 (para-aortic) lymphadenectomy. Current NCCN treatment guidelines recommend regional (D2) node resection. The role of preoperative (neoadjuvant) or postoperative (adjuvant) chemotherapy or radiochemotherapy after curative resection is controversial. In the United States, adjuvant chemoradiotherapy (commonly 5-FU and leucovorin) is recommended, especially for patients with lymph node involvement. Outside of the United States, adjuvant chemotherapy alone (commonly, epirubicin, cisplatin, and 5-FU) is used. Tumors arising in the cardia are treated similar to esophageal cancer.

Palliative Modalities

Many patients will be found either preoperatively or at the time of surgical exploration to have advanced disease that is not amenable to "curative" surgery due to peritoneal or distant metastases or local invasion of other organs. In some of these cases, palliative resection of the tumor nonetheless may be indicated to alleviate pain, bleeding, or obstruction. For patients with unresectable disease, gastrojejunostomy may be indicated to prevent obstruction. Alternatively, unresected tumors may be treated with endoscopic laser or stent therapy, radiation therapy, or angiographic embolization to relieve bleeding or obstruction. Chemotherapy may be considered in patients with metastatic disease who still have good functional status and expected survival of several months. Although there is no consensus on optimal therapy, a combination of epirubicin, cisplatin, and 5-FU commonly is used. A large 2008 trial assigned patients with advanced esophageal and gastric cancer to one of four triplet therapies: epirubicin and cisplatin plus either fluorouracil (ECF) or capecitabine (ECX) or epirubicin and oxaliplatin plus either fluorouracil (EOF) or capecitabine (EOX). No difference in median survival was found among the four regimens (9-11 months); however, toxicity in patients treated with oxaliplatin.

Prognosis

The long-term survival of gastric carcinoma is less than 15%. However, 5-year survival in patients who undergo successful curative resection is over 45%. Survival is related to tumor stage, location, and histologic features. Stage I and stage II tumors resected for cure have a greater than 50% long-term survival. Patients with stage III tumors have a poor prognosis (< 20% long-term survival) and should be considered for enrollment in clinical trials. Tumors of the diffuse type have a worse prognosis than the intestinal type. Tumors of the proximal stomach (fundus and cardia) carry a far worse prognosis than distal lesions. Even with apparently localized disease, proximal tumors have a 5-year survival of less than 15%. For those whose disease progresses despite therapy, meticulous efforts at palliative care are essential (see Chapter 5: Palliative Care & Pain Management).

When to Refer

- Patients with dysphagia, weight loss, protracted vomiting, iron-deficiency anemia, or new-onset of dyspepsia (especially if age 55 years or older or associated with other alarm symptoms) in whom gastric cancer is suspected should be referred to a gastroenterologist for endoscopic screening.
- Patients should be referred to a surgeon for attempt at curative resection in stage I, II, or III cancer.
- Patients with unresectable or metastatic disease should be referred to an oncologist for consideration of adjuvant chemotherapy or chemoradiotherapy after curative resection or palliative therapy.

When to Admit

Patients with advanced gastric cancer causing protracted vomiting, inability to maintain oral intake, or acute bleeding should be admitted.

Gastric Lymphoma

Essentials of Diagnosis

- Symptoms of dyspepsia, weight loss, or anemia.
- Variable abnormalities on upper gastrointestinal series or endoscopy including thickened folds, ulcer, mass or infiltrating lesions; diagnosis established by endoscopic biopsy.
- Abdominal CT and EUS required for staging.

General Considerations

Gastric lymphomas may be primary (arising from the gastric mucosa) or may represent a site of secondary involvement in patients with nodal lymphomas. Distinguishing advanced primary gastric lymphoma with adjacent nodal spread from advanced nodal lymphoma with secondary gastric spread can be problematic. Because the prognosis and treatment of primary and secondary gastric lymphomas are entirely different, the distinction is important. Primary lymphoma is the second most common gastric malignancy, accounting for 3% of cancers. More than 95% of these are non-Hodgkin B cell lymphomas. Most primary gastric lymphomas are believed to arise from mucosa-associated lymphoid tissue (MALT). Primary gastric lymphomas comprise two main types: 60% are diffuse large B-cell lymphomas (previously called "high-grade" MALT lymphomas) and

40% are marginal zone B-cell lymphomas of the MALT-type (previously call "low-grade" MALT lymphoma). B cells of nodal origin may be distinguished from those derived from MALT (CD19 and CD20 positive).

Infection with *H pylori* is an important risk factor for the development of primary gastric lymphoma. Chronic infection with *H pylori* causes an intense lymphocytic inflammatory response that may lead to the development of lymphoid follicles. Over 85% of low-grade primary gastric MALT-type lymphomas are associated with *H pylori* infection. It is hypothesized that chronic antigenic stimulation may result in a monoclonal lymphoproliferation that may culminate in low-grade or high-grade lymphoma.

Clinical Findings

The clinical presentation and endoscopic appearance of gastric lymphoma are similar to those of adenocarcinoma. Most patients have abdominal pain, weight loss, or bleeding. Patients with diffuse large B-cell lymphoma are more likely to have systemic symptoms and advanced tumor stage. At endoscopy, lymphoma may appear as an ulcer, mass, or diffusely infiltrating lesion. The diagnosis is established with endoscopic biopsy. All patients should undergo staging with abdominal and chest CT. EUS is the most sensitive test for determining the level of invasion and presence of perigastric lymphadenopathy.

Treatment

Nodal lymphomas with secondary gastrointestinal involvement usually present at an advanced stage with widely disseminated disease and are seldom curable. Their treatment is addressed in Chapter 13: Blood Disorders. Treatment of primary gastric lymphomas depends on the tumor histology, grade, and stage. Marginal B-cell lymphomas of the MALT type may be low-grade and localized to the stomach wall (stage IE) and have an excellent prognosis. Where available, EUS should be performed to accurately determine tumor stage. Patients with primary gastric MALT-lymphoma should be tested for *H pylori* infection and treated if positive. Complete lymphoma regression after successful *H pylori* eradication occurs in 75% of cases of stage IE low-grade lymphoma. Remission may take as long as a year. Patients with localized (stage IE) marginal zone MALT-type lymphomas who either are not infected with *H pylori* or do not respond to eradication therapy may be treated with radiation therapy. Patients with diffuse large cell (high-grade) lymphomas and patients with MALT-type lymphomas that extend beyond the gastric wall should be treated with combination chemotherapy (eg, CHOP with rituximab). Because of a low risk of perforation with either radiation therapy or chemotherapy, surgical resection is no longer recommended. The long-term survival of primary gastric lymphoma for stage I is over

85% and for stage II is 35–65%.

Gastric Carcinoid Tumors

Gastric carcinoids are rare neuroendocrine tumors that make up less than 1% of gastric neoplasms. They may occur sporadically or secondary to chronic hypergastrinemia that results in hyperplasia and transformation of enterochromaffin cells in the gastric fundus. Sporadic carcinoids account for 20% of gastric carcinoids. Most are solitary, over 2 cm in size, and have a strong propensity for metastatic spread. Most sporadic carcinoids already have carcinoid syndrome and hepatic or pulmonary metastatic involvement at initial presentation. Localized sporadic carcinoids should be treated with radical gastrectomy.

The majority of carcinoids caused by hypergastrinemia occur in association with either pernicious anemia (75%) or Zollinger-Ellison syndrome (5%). Carcinoids associated with Zollinger-Ellison syndrome occur almost exclusively in patients with MEN 1, in which loss of 11q13 has been reported. Carcinoids caused by hypergastrinemia tend to be multicentric, less than 1 cm in size, and have a low potential for metastatic spread or development of carcinoid syndrome. Small lesions may be successfully treated with endoscopic resection followed by periodic endoscopic surveillance. Antrectomy reduces serum gastrin levels and may lead to regression of small tumors. Patients with large or multiple carcinoids should undergo surgical tumor resection (see Carcinoid Tumors, below).

Landry CS et al. A proposed staging system for gastric carcinoid tumors based on an analysis of 1,543 patients. Ann Surg Oncol. 2009 Jan;16(1):51–60. [PMID: 18953609]

Gastrointestinal Mesenchymal Tumors

Gastrointestinal mesenchymal tumors occur throughout the gastrointestinal tract, but approximately two-thirds occur in the stomach. These tumors (which include stromal tumors, leiomyomas, and schwannomas) derive from mesenchymal stem cells and have an epithelioid or spindle cell histologic pattern, resembling smooth muscle. The most common stromal tumors are gastrointestinal stromal tumors ("GISTs"), which appear to originate from interstitial cells of Cajal. GISTs occur throughout the gastrointestinal tract but most commonly in the stomach (50%) and small intestine (30%). About 85–90% of GISTs have mutations in KIT, a receptor tyrosine kinase that binds stem cell factor, or a homologous tyrosine kinase, platelet-derived growth factor alpha that lead to constitutive activation. Approximately 90% of stromal tumors stain positively for CD117 (part of the KIT protein). Other mesenchymal tumors such as leiomyomas, which derive from smooth muscle cells, stain negative for CD117. Mesenchymal tumors may be discovered incidentally on imaging studies or endoscopy or may cause symptoms, mainly obstruction by large tumors or acute or chronic bleeding due to central ulceration within the tumor. At endoscopy, they appear as a submucosal mass that may have central umbilication or ulceration. EUS (possibly with guided FNA biopsy) is the optimal study for diagnosing mesenchymal tumors and distinguishing them from other submucosal lesions. While almost all GISTs have malignant potential, the risk of developing metastasis is related to the tumor size and mitotic index (> 5 mitoses per high-powered field);

however, mitotic index can only be assessed after resection. It is difficult to distinguish with certainty benign from malignant (sarcoma) tumors before resection by EUS appearance or FNA. In general, lesions that are smaller than 2 cm, have a smooth border, and have a homogeneous echo pattern on EUS are more likely benign.

Surgery is recommended for all patients with tumors that are symptomatic, 2 cm, are increasing in size, or have an EUS appearance suspicious for malignancy. PET-CT scan should be obtained prior to surgery to look for metastatic disease. The management of asymptomatic benign-appearing lesions 2 cm in size is problematic. Because of a low risk of malignancy, surgical resection should be considered in younger, otherwise healthy patients; however, other patients may be followed up with serial EUS examinations or, in selected cases, endoscopic resections. There is a high risk of metastasis or recurrence when tumors are larger than 5 cm, have an irregular border or cystic spaces, and have increased mitotic activity (more than five mitoses per high-power field). These high-risk tumors have a 50% 5-year survival rate after complete surgical resection. Metastatic tumors are aggressive and carry a poor prognosis. The tyrosine kinase inhibitor imatinib induces disease control in up to 85% of patients with metastatic disease with a progression free-survival of 20–24 months. Resistant tumors may respond to another tyrosine kinase inhibitor, sunitinib.

Malignancies of the Small Intestine

Adenocarcinoma

These are aggressive tumors that occur most commonly in the duodenum or proximal jejunum. The ampulla of Vater is the most common site of small bowel carcinoma, and the incidence of ampullary carcinoma is increased more than 200-fold in patients with FAP. Ampullary carcinoma may present with jaundice due to bile duct obstruction or bleeding. Surgical resection of early lesions is curative in up to 40% of patients. Periodic endoscopic surveillance to detect early ampullary neoplasms therefore is recommended in patients with this disorder.

Nonampullary adenocarcinoma of the small intestine accounts for < 3% of all gastrointestinal cancers but one-third of small bowel cancers. Peak incidence is in the sixth decade. Most cases present with symptoms of obstruction, acute or chronic bleeding, or weight loss. The majority of small bowel cancers have already metastasized at the time of diagnosis. Resection is recommended for control of symptoms. The role of adjuvant therapy is unclear. The prognosis is poor with a 5-year overall survival of 20–30%. Patients with Crohn disease have an increased risk of small intestine adenocarcinoma, most commonly in the ileum, which may be difficult to distinguish from disease-related fibrous strictures.

Lymphoma

Gastrointestinal lymphomas may arise in the gastrointestinal tract or involve it secondarily with disseminated disease. In Western countries, primary gastrointestinal lymphomas account for 5% of lymphomas and 20% of small bowel malignancies. They occur most commonly in the distal small intestine. The majority are non-Hodgkin high-grade marginal zone B cell lymphomas. There is an increased incidence of small intestinal lymphomas in patients with AIDS, immunosuppressive therapy, and Crohn disease. T cell lymphomas may arise in patients with celiac sprue. In the

Middle East, lymphomas may arise in the setting of immunoproliferative small intestinal disease. In this condition, there is diffuse lymphoplasmacytic infiltration with IgA-secreting B lymphocytes of the mucosa and submucosa that results in weight loss, diarrhea, and malabsorption, which may lead to lymphomatous transformation. A characteristic feature of the disease is the presence of heavy chains in the serum in 70% produced by clones of IgA plasma cells. Other types of intestinal lymphomas include mantle cell and Burkitt.

Presenting symptoms or signs of primary lymphoma include abdominal pain, weight loss, nausea and vomiting, distention, anemia, and occult blood in the stool. Fevers are unusual. Protein-losing enteropathy may result in hypoalbuminemia, but other signs of malabsorption are unusual. Barium radiography or CT enterography helps localize the site of the lesion. The diagnosis requires endoscopic, percutaneous, or laparoscopic biopsy. To determine tumor stage, patients must undergo chest and abdominal CT, and bone marrow biopsy.

Treatment depends on the tumor histologic grade and stage of disease. Resection of primary intestinal lymphoma, if feasible, is usually recommended. Even in cases of stage III or stage IV disease, surgical debulking may improve survival. In patients with limited disease (stage IE) in whom resection is performed, the role of adjuvant chemotherapy is unclear. Most patients with more extensive disease are treated with combination chemotherapy (eg, CHOP with rituximab) with or without radiation therapy.

Carcinoid Tumors

Essentials of Diagnosis

- Majority are asymptomatic and discovered incidentally at endoscopy or surgery
- Carcinoid syndrome occurs in less than 10%; hepatic metastases are generally present.
- Risk of metastasis related to tumor size and location.

General Considerations

Gastrointestinal carcinoids are slow growing neuroendocrine tumors that may arise anywhere in the gastrointestinal tract but most commonly occur in the small intestine (30%), rectum (12%), colon (8%), appendix (8%), and stomach (10–30%; see above). Carcinoids may contain a variety of hormones, including serotonin, somatostatin, gastrin, and substance P that may or may not be secreted, and usually display immunoreactivity to chromogranin A. Although many carcinoids behave in an indolent fashion, the overall 5-year survival rate for patients with carcinoids is 50%, suggesting that most are malignant. The risk of metastatic spread is closely related to tumor size and tumor location. Many small carcinoids are detected incidentally at endoscopy or autopsy. It is not possible by histologic examination to distinguish benign from malignant disease. The best indicator of prognosis is evidence of invasive growth and the presence of regional or distant metastasis.

Carcinoids account for up to one-third of small intestinal tumors. Small intestinal carcinoids most commonly arise in the ileum. Up to one-third are multicentric. Although 60% are less than 2 cm in size, even these small carcinoids may metastasize. Almost all small intestinal carcinoids over 2 cm are associated with metastasis.

Appendiceal carcinoids are identified in 0.3% of appendectomies, usually as an incidental finding. Almost 80% of these tumors are less than 1 cm in size, and 90% are less than 2 cm. Rectal carcinoids are usually detected incidentally as submucosal nodules during proctoscopic examination. Rectal carcinoids less than 1 cm and appendiceal carcinoids less than 2 cm virtually never metastasize and are treated effectively with local excision or simple appendectomy. Tumors larger than 2 cm are associated with the development of metastasis in over 20% of appendiceal carcinoids and 10% of rectal carcinoids. Hence, in younger patients who are good candidates for surgery, a more extensive cancer resection operation is warranted.

Clinical Findings

Symptoms and Signs

Most smaller lesions (less than 1–2 cm) are asymptomatic and difficult to detect by endoscopy or imaging studies. When carcinoids present with symptoms, most are at an advanced and incurable stage. Through local extension or metastasis to mesenteric lymph nodes, carcinoids engender a fibroblastic reaction with contraction and kinking of the bowel or encasement of mesenteric vessels. Small intestinal carcinoids may present with abdominal pain, bowel obstruction, or bowel infarction. Abdominal CT or enterography may reveal kinking, but because the lesion is extraluminal the diagnosis may be overlooked for several years. Appendiceal and rectal carcinoids usually are small and asymptomatic but large lesions can cause bleeding, obstruction, or altered bowel habits. Carcinoid involvement of the heart (resulting in right-sided valvular lesions) is a late manifestation of metastatic disease. **Carcinoid syndrome** occurs in less than 10% of patients. More than 90% of patients with carcinoid syndrome have hepatic mestastases, usually from carcinoids of small bowel origin. About 10% of patients with carcinoid syndrome have primary bronchial or ovarian tumors without hepatic metastases. Carcinoid syndrome is caused by tumor secretion of hormonal mediators. The manifestations include facial flushing, edema of the head and neck (especially with bronchial carcinoid), abdominal cramps and diarrhea, bronchospasm, cardiac lesions (pulmonary or tricuspid stenosis or regurgitation), and telangiectases.

Laboratory Findings

Plasma chromogranin A (CgA) is the most sensitive screening test for small intestine carcinoids, although its sensitivity for small, localized tumors is unknown. CgA is elevated in almost 90% of patients with advanced small bowel carcinoid. Urinary 5-hydroxyindoleacetic acid (5-HIAA) or platelet serotonin levels are also elevated in patients with metastatic carcinoid; however, these tests are less sensitive than CgA. There is increased urinary 5-HIAA in carcinoid syndrome; symptomatic patients usually excrete more than 25 mg of 5-HIAA per day in the urine. Ideally, all drugs should be withheld for several days prior to the urine collection.

Imaging

Abdominal CT may demonstrate a mesenteric mass with tethering of the bowel, lymphadenopathy, and hepatic metastasis. Somatostatin receptor scintigraphy, which is positive in up to 90% of patients with metastatic carcinoid, is superior to all other imaging modalities for the diagnosis of primary and metastatic lesions. Almost all patients with carcinoid syndrome have obvious signs of cancer with liver metastasis on abdominal imaging.

Treatment

Small intestinal carcinoids are extremely indolent tumors with slow spread. Patients with disease confined to the small intestine should have local excision, for which the cure rate exceeds 85%. In patients with resectable disease who have lymph node involvement, the 5-year disease-free survival is 80%; however, by 25 years, less than 25% remain disease free. Even patients with hepatic metastases may have an indolent course with a median survival of 3 years. In patients with advanced disease, therapy should be deferred until the patient is symptomatic. Surgery should be directed toward palliation of obstructive symptoms.

In patients with carcinoid syndrome, resection of hepatic metastases may provide dramatic improvement. The somatostatin analog octreotide (150–500 mcg subcutaneously three times daily) inhibits hormone secretion from the carcinoid tumor, resulting in dramatic relief of symptoms of carcinoid syndrome, including diarrhea or flushing, in 90% of patients for a median period of 1 year. Thereafter, many patients stop responding to octreotide. Hepatic artery occlusion and chemotherapy may provide symptomatic improvement in some patients with hepatic metastases. Emergency therapy for patients with symptomatic bronchial carcinoids consists of giving prednisone, 15–30 mg orally daily.

Small Intestine Sarcoma

Most small intestine sarcomas arise from stromal tumors that stain positive for CD117; a minority arise from smooth muscle tumors (leiomyosarcomas) (see Gastrointestinal Mesenchymal Tumors above).

Kaposi sarcoma was at one time a common complication in AIDS, but the incidence is declining with highly active antiretroviral therapy (HAART). It is strongly associated with infection with human herpesvirus 8. Lesions may be present anywhere in the intestinal tract. Visceral involvement usually is associated with cutaneous disease. Most lesions are clinically silent; however, large lesions may be symptomatic. Interferon- induces regression in up to one-third of patients who have a CD4 cell count of > 200/mcL. Widespread involvement may be best treated by systemic chemotherapy using combinations of vincristine, bleomycin, or doxorubicin, to which the tumor is very responsive.

Colorectal Cancer

Essentials of Diagnosis

- Personal or family history of adenomatous polyps or colorectal cancer are important risk factors.
- Symptoms or signs depend on tumor location.
- Proximal colon: fecal occult blood, anemia.
- Distal colon: change in bowel habits, hematochezia.
- Diagnosis established with colonoscopy.

General Considerations

Colorectal cancer is the second leading cause of death due to malignancy in the United States. Approximately 6% of Americans will develop colorectal cancer and 40% of those will die of the disease. In 2008, there were an estimated 149,000 new cases and 50,000 deaths. Colorectal cancers are almost all adenocarcinomas, which tend to form bulky exophytic masses or annular constricting lesions. Slightly less than 50% of cancers are located distal to the splenic flexure (within the descending colon or rectosigmoid region). It is currently believed that the majority of colorectal cancers arise from malignant transformation of an adenomatous polyp. Adenomatous polyps that are "advanced" (ie, adenomas at least 1 cm in size, adenomas with villous features, or adenomas with high-grade dysplasia) are associated with a greater risk of cancer.

Approximately 85% of sporadic colorectal cancers have loss of function of one or more tumor suppressor genes (eg, *p53, APC,* or *DCC)* due to a combination of spontaneous mutation of one allele combined with chromosomal instability and aneuploidy (abnormal DNA content) that leads to deletion and loss of heterozygosity of the other allele (eg, 5q, 17q, or 18p deletion). Approximately 15% of colorectal cancers have microsatellite instability due to inactivation of DNA mismatch repair genes. This is most commonly an acquired defect caused by hypermethylation of the promoter region of the MLH1 gene, but may be an indicator of unrecognized HNPCC (see Chapter 15: Gastrointestinal Disorders). Colon cancer with high microsatellite instability have distinct clinical and pathologic characteristics, including diploid DNA content, predominance in the proximal colon, poor differentiation, and more favorable prognosis.

Risk Factors

A number of factors increase the risk of developing colorectal cancer. Recognition of these has impact on screening strategies. However, 75% of all cases occur in people with no known predisposing factors.

Age

The incidence of colorectal cancer rises sharply after age 45 years, and 90% of cases occur in persons over the age of 50 years.

Family History of Neoplasia

A family history of colorectal cancer is present in 20% of patients with colon cancer. Hereditary factors are believed to contribute to 20–30% of colorectal cancers; however, the genes responsible for most of these cases have not yet been identified. Up to 5% of colorectal cancers are caused by inherited germline mutations resulting in polyposis syndromes or hereditary nonpolyposis colorectal cancer (HNPCC) (see Chapter 15: Gastrointestinal Disorders). Approximately 6% of the Ashkenazic Jewish population has a missense mutation in the *APC* gene *(APC I1307K)* that confers a modestly increased lifetime risk of developing colorectal cancer (OR 1.4–1.9) but phenotypically resembles sporadic colorectal cancer rather than FAP. Genetic screening is available, and patients harboring the mutation merit intensive screening.

A family history of colorectal cancer or adenomatous polyps is one of the most important risk factors for colorectal cancer. The risk of colon cancer is proportionate to the number and age of affected first-degree family members with colon neoplasia. People with one first-degree family member with colorectal cancer have an increased risk approximately two times that of the general population; however, the risk is almost four times if the family member's cancer was diagnosed at < 45 years of age. Patients with two first-degree relatives have a fourfold, or 25–30% lifetime, risk of developing colon cancer. First-degree relatives of patients with adenomatous polyps also have a twofold increased risk for colorectal neoplasia, especially if the polyp was large (10 mm) or detected before age 60 years.

Inflammatory Bowel Disease

The risk of adenocarcinoma of the colon begins to rise 7–10 years after disease onset in patients with ulcerative colitis and Crohn colitis. The cumulative risk approaches 5–10% after 20 years and 20% after 30 years. Chronic treatment with 5-ASA agents and folate is associated with a lower risk of cancer in patients with ulcerative colitis.

Dietary Factors and Chemoprevention

In epidemiologic studies, diets rich in fats and red meat are associated with an increased risk of colorectal adenomas and cancer, whereas diets high in fruits, vegetables, and fiber are associated with a decreased risk. However, prospective, randomized controlled trials failed to demonstrate a risk reduction in the recurrence of adenomatous polyps after treatment with a diet low in fat and high in fiber, fruits, and vegetables, or with fiber supplementation. Calcium carbonate (3 g/d) has been shown in large cohort studies as well as small prospective trials to yield a modest reduction in the relative risk of developing colorectal neoplasia; however, a 2006 prospective study of 36,000 women did not show a protective benefit of calcium (500 mg) and vitamin D (200 international units twice daily) in preventing colon cancer. Similarly, the risk of colon cancer appears to be decreased in persons taking folic acid supplements, but a 2007 prospective trial conducted in patients with a history of adenomas found that folate supplementation did not reduce the incidence of adenoma recurrence compared with placebo. The antioxidant vitamins A, C, E, and beta carotene also have not been shown to be of benefit in prospective controlled studies.

A US Preventive Services Task Force meta-analysis of cohort and case-control studies suggest that prolonged (> 6 years) regular use of aspirin (at least 325 mg twice weekly) and NSAIDs is associated with a 22–33% relative risk reduction in the incidence of colorectal cancer. Two prospective, blinded clinical trials have shown that daily low-dose aspirin (80–325 mg) reduces the number of recurrent adenomas at 1–3 years in patients with a history of colorectal adenomas or cancer; however, two large randomized controlled trials in the United States did not demonstrate a reduction in colorectal cancer incidence in patients taking low-dose aspirin over a 5–10 years. Because long-term aspirin use is associated with a low incidence of serious complications (gastrointestinal hemorrhage, stroke), the US Preventive Services Task Force concluded that it should not be prescribed as a chemopreventive agent in people without polyps or with small adenomas unless there are other medical indications. Long-term administration of low-dose aspirin may be considered in patients with a personal or family history of colorectal cancer or advanced adenomas; however, they do not obviate the need for colonoscopy screening and surveillance.

Other Factors

The incidence of colon adenocarcinoma is higher in blacks than in whites. It is unclear whether this is due to genetic or socioeconomic factors (eg, diet or reduced access to screening). Diabetes, metabolic syndrome, obesity, and cigarette smoking are associated with a modest increase in cancer risk.

Clinical Findings

Symptoms and Signs

Adenocarcinomas grow slowly and may be present for several years before symptoms appear. However, some asymptomatic tumors may be detected by the presence of fecal occult blood (see Colorectal Cancer Screening, below). Symptoms depend on the location of the carcinoma. Chronic blood loss from right-sided colonic cancers may cause iron deficiency anemia, manifested by fatigue and weakness. Obstruction, however, is uncommon because of the large diameter of the right colon and the liquid consistency of the fecal material. Lesions of the left colon often involve the bowel circumferentially. Because the left colon has a smaller diameter and the fecal matter is solid, obstructive symptoms may develop with colicky abdominal pain and a change in bowel habits. Constipation may alternate with periods of increased frequency and loose stools. The stool may be streaked with blood, though marked bleeding is unusual. With rectal cancers, patients note tenesmus, urgency, and recurrent hematochezia. Weight loss is uncommon. Physical examination is usually normal except in advanced disease. A mass may be palpable in the abdomen. The liver should be examined for hepatomegaly, suggesting metastatic spread. For cancers of the distal rectum, digital examination is necessary to determine whether there is extension into the anal sphincter or fixation, suggesting extension to the pelvic floor.

Laboratory Findings

A complete blood count is obtained to look for evidence of anemia. Elevated liver function tests are suspicious for metastatic disease. Carcinoembryonic antigen (CEA) should be measured in all patients with proved colorectal cancer. A preoperative CEA level > 5 ng/mL is a poor prognostic indicator. After complete surgical resection, CEA levels should normalize; persistently elevated levels suggest the presence of persistent disease and warrant further evaluation.

Colonoscopy

Colonoscopy is the diagnostic procedure of choice in patients with a clinical history suggestive of colon cancer or in patients with an abnormality suspicious for cancer detected on radiographic imaging. Colonoscopy permits biopsy for pathologic confirmation of malignancy (Plate 120). In patients in whom colonoscopy is unable to reach the cecum (< 5% of cases) or when a nearly obstructing tumor precludes passage of the colonoscope, barium enema or CT colonography examination should be performed.

Imaging

Clinicians obtain an abdominal and pelvic CT scan to assist in preoperative staging. CT scans may demonstrate distal metastases but are less accurate in the determination of the level of local tumor extension (T stage) or lymphatic spread (N stage). Intraoperative assessment of the liver by direct palpation and ultrasonography is more accurate than CT scanning for the detection of hepatic metastases. For rectal cancer, pelvic MRI or endorectal ultrasonography provides important accurate information about the depth of penetration of the cancer through the rectal wall and pararectal lymph nodes that may guide preoperative (neoadjuvant) chemoradiotherapy and operative management. A chest CT scan should also be obtained because the systemic blood supply of the distal rectum may promote distal tumor metastasis outside the abdomen. PET is useful to determine recurrent colorectal cancer but currently is not used for staging of primary tumors.

Staging

The TNM system is the commonly used classification to stage colorectal cancer. Staging is important not only because it correlates with the patient's long-term survival but also because it is used to determine which patients should receive adjuvant therapy (eTable 39–4.1).

eTable 39–4.1. Staging of colorectal cancer.

Joint Committee Classification	**TNM**			**Dukes Class**[1]
Stage 0				
Carcinoma in situ		N0	M0	
Stage I				

Tumor invades submucosa	T1	N0	M0	Dukes A
Tumor invades muscularis propria	T2	N0	M0	Dukes B_1
Stage II				
Tumor invades into subserosa or into nonperitonealized pericolic or perirectal tissues	T3	N0	M0	Dukes B_1 or B_2
Tumor perforates the visceral peritoneum or directly invades other organs or structures	T4	N0	M0	Dukes B_2
Stage III				
Any degree of bowel wall perforation with lymph node metastasis				
One to three pericolic or perirectal lymph nodes involved	Any T	N1	M0	Dukes C_1
Four or more pericolic or perirectal lymph nodes involved	Any T	N2	M0	Dukes C_2
Metastasis to lymph nodes along a vascular trunk	Any T	N3	M0	
Stage IV				

Presence of distant metastasis	Any T	Any N	M1	Dukes D

[1] Gastrointestinal Tumor Study Group modification of Dukes classification.

Differential Diagnosis

The nonspecific symptoms of colon cancer may be confused with those of irritable bowel syndrome, diverticular disease, ischemic colitis, inflammatory bowel disease, infectious colitis, and hemorrhoids. Neoplasm must be excluded in any patient over age 40 years who reports a change in bowel habits or hematochezia or who has an unexplained iron deficiency anemia or occult blood in the stools.

Treatment

Resection of the primary colonic or rectal cancer is the treatment of choice for almost all patients who have resectable lesions and can tolerate general anesthesia. Multiple studies demonstrate that minimally invasive, laparoscopically assisted colectomy results in similar outcomes and rates of recurrence to open colectomy. Regional dissection of at least 12 lymph nodes should be performed to determine staging, which guides decisions about adjuvant therapy. Even patients with extensive metastatic disease may benefit from resection of the colonic tumor to reduce the likelihood of intestinal obstruction or serious bleeding.

For rectal carcinoma, the operative approach depends on the level of the tumor above the anal verge, the size and depth of penetration, and the patient's overall condition. Clinical staging by endorectal ultrasound or MRI with endorectal coil is important in guiding the clinical approach. In carefully selected patients with small, mobile (< 4 cm), well-differentiated T1 or T2 rectal tumors that are less than 8 cm from the anal verge and that appear on endosonography to be localized to the rectal wall, transanal excision may be performed. This approach avoids laparotomy and spares the rectum and anal sphincter, preserving normal bowel continence. All other patients will require either a low anterior resection with a colorectal anastomosis or an abdominoperineal resection with a colostomy, depending on how far above the anal verge the tumor is located and the extent of local tumor spread. Careful dissection of the entire mesorectum at the time of surgery has been shown to reduce local recurrence to 8%. With improvements in surgical stapling techniques, it is possible to perform low anterior resection provided there is a margin of at least 2 cm of normal tissue below the tumor. Although low resections obviate a colostomy, they are associated with increased immediate postsurgical complications (leak, dehiscence, stricture) and defecatory complaints (increased stool frequency, defecatory problems, and incontinence). With unresectable rectal cancer, the patient may be palliated with a diverting colostomy, laser fulguration, or placement of an expandable wire stent.

Adjuvant Therapy for Colon Cancer

Adjuvant chemotherapy and radiotherapy have been demonstrated to improve overall and tumor-free survival in selected patients with colon cancer.

Stage I

Because of the excellent 5-year survival rate (90–100%), no adjuvant therapy is recommended.

Stage II (node-negative disease)

The expected 5-year survival rate is 80%. A benefit from adjuvant chemotherapy has not been demonstrated in most controlled trials for stage II colon cancer (see discussion for stage III disease). However, otherwise healthy patients with stage II disease that is at higher risk for recurrence (perforation, T4, poor differentiation on histology) may benefit from adjuvant chemotherapy.

Stage III (node-positive disease)

With surgical resection alone, the expected 5-year survival rate is 30–50%. Postoperative adjuvant chemotherapy significantly increases disease-free survival as well as overall survival by up to 30% and is recommended for all patients. In stage III colorectal cancer, patients treated for 6 months with intravenous 5-FU and leucovorin (folinic acid) who have one to three involved nodes have a 5-year survival of 65%, and those with more than three involved nodes have a 5-year survival of up to 40%. Capecitabine is an oral 5-FU analog that obviates the need for intravenous infusions. Monotherapy with capecitabine yields a similar rate of disease-free survival with a lower rate of serious side effects (except for hand-foot syndrome) compared with intravenous 5-FU and leucovorin. Oxaliplatin is an important addition to combination adjuvant therapy. Large, well-designed studies of adjuvant therapy for stage III colon cancer reported a higher rate of disease-free survival at 5 years for patients treated with a combination of oxaliplatin, fluorouracil, and leucovorin (FOLFOX) (66%) than with fluorouracil and leucovorin (FL) alone (59%). The addition of oxaliplatin is associated with an increased incidence of diarrhea and sensory neuropathy, which generally is reversible. Based on these studies, FOLFOX currently is the preferred adjuvant therapy for most patients with Stage III disease. Current studies are evaluating oral capecitabine in combination with oxaliplatin. The role of combination adjuvant therapy of FOLFOX plus a biologic agent (bevacizumab, cetuximab, or panituxumab) also is under investigation.

Stage IV (metastatic disease)

Approximately 20% of patients have metastatic disease at the time of initial diagnosis, and another 30% eventually develop metastasis. A subset of these patients have limited disease that is potentially curable with surgical resection. Resection of isolated (one to three) liver or lung metastases may result in long-term (over 5 years) survival in 35–55% of cases. For those with unresectable hepatic metastases, local ablative techniques (cryosurgery, radiofrequency or microwave coagulation, embolization, hepatic intra-arterial chemotherapy) may provide long-term tumor control. The majority of patients with metastatic disease do not have resectable (curable) disease. In the absence of other treatment, the median survival is only 6 months. The goals of therapy are to slow tumor progression while maintaining a reasonable quality of life for as long as possible. Currently, either FOLFOX (the addition of oxaliplatin to 5-FU and folinic acid) or FOLFIRI (the addition of irinotecan to 5-FU and folinic acid) is the preferred first-line treatment regimens for most patients with metastatic colorectal cancer, increasing median survival to 15–20 months. For convenience, oral capecitabine (instead of intravenous 5-FU and leucovorin) can be used in combination with oxaliplatin; however, combination with irinotecan should not be used due to increased toxicity (diarrhea). The role of combination therapy with both oxaliplatin and irinotecan is under investigation. The role of biologic agents (cetuximab, panitumumab, and bevacizumab) is rapidly evolving. Cetuximab and panitumumab are monoclonal antibodies to EGFR; bevacizumab is a monoclonal antibody to VEGF. Combination therapy with bevacizumab and FOLFOX or FOLFIRI prolong mean survival 2–5 months compared with either regimen alone. Therefore, many oncologists are now using one of these combinations for initial therapy of metastatic disease. Bevacizumab may cause serious side effects, including arterial thromboembolic events, bowel perforation, or serious bleeding, in up to 5% of patients.

When disease progresses with FOLFOX or FOLFIRI (often in conjunction with bevacizumab), it is reasonable to switch to the alternative regimen. Patients progressing with one regimen may respond to the alternative regimen, prolonging mean survival to > 20 months. The anti-EGFR agents cetuximab and panitumumab may be used in patients whose disease has progressed despite first-line or second-line therapy. Both agents have modest efficacy when used as single agents for second-line therapy; however, a 2008 study reported that patients whose tumors had *K-ras* mutations did not benefit from anti-EGFR therapy, whereas patients with wild-type *K-ras* had 5 months median improved survival. Patients being considered for anti-EGFR therapy should therefore undergo *K-ras* testing. Cetuximab in combination with

FOLFOX or FOLFIRI appears to provide a modest increase in median survival; however, the efficacy of these regimens versus bevacizumab-containing regimens is under investigation. The role of combination therapy of bevacizumab plus cetuximab or panitumumab with or without other agents requires further study.

Adjuvant Therapy for Rectal Cancer

Compared with colon cancer, rectal cancer has lower long-term survival rates and significantly higher rates of local tumor recurrence (25%) due to the difficulty of achieving adequate surgical resection margins. When initial imaging studies suggest stage I disease, surgery may be performed first. Combination therapy with fluorouracil (a radiation sensitizing agent) and radiation has been shown to improve the disease-free survival rate and to decrease pelvic recurrence and is recommended for all patients with stage II and stage III rectal cancers. It has long been controversial whether chemoradiation should be administered preoperatively ("neoadjuvant") or postoperatively ("adjuvant"). In 2004, a large, randomized controlled trial reported that preoperative therapy led to better patient treatment compliance, reduced local recurrence and toxicity, and a higher number of sphincter-preserving resections. Therefore, preoperative chemoradiation is recommended for patients with distal rectal cancers that are determined to be stage II or III by endorectal ultrasound or MRI. Following surgical resection with total mesorectal excision, fluorouracil-based therapy may be administered for an additional 4 months.

Follow-Up after Surgery

Patients who have undergone resections for cure are followed closely to look for evidence of symptomatic or asymptomatic tumor recurrence that may be amenable to curative resection in a small number of patients. The optimal cost-effective strategy is not clear. Two randomized trials reported that intense follow-up with yearly colonoscopy, abdominal CT, and chest radiography did not improve overall outcome compared with most standard follow-up protocols. Patients should be evaluated every 3–6 months for 3–5 years with history, physical examination, and CEA determinations. Patients who had a complete preoperative colonoscopy should undergo another colonoscopy 1 year after surgical resection. Patients who did not undergo full colonoscopy preoperatively should undergo colonoscopy within 3–6 months postoperatively to exclude other synchronous colorectal neoplasms and 1 year thereafter. Thereafter, surveillance colonoscopy should be performed every 3–5 years to look for metachronous polyps or cancer. Because of the high incidence of local tumor recurrence in patients with rectal cancer, sigmoidoscopy should be performed every 3–6 months for 3 years. New onset of symptoms or a rising CEA warrants investigation with chest and abdominal CT to look for recurrent or metastatic disease that may be amenable to therapy. For patients with a rising CEA with unrevealing CT imaging, a PET scan is more sensitive for the detection of occult metastatic disease.

Prognosis

The stage of disease at presentation is the most important determinant of long-term survival: stage I, > 90%; stage II, 70–85%; stage III with fewer than four positive lymph nodes, 67%; stage III with more than four positive lymph nodes, 33%; and stage IV, 5–7%. For each stage, rectal cancers have a worse prognosis. For those patients whose disease progresses despite therapy, meticulous efforts at palliative care are essential (see Chapter 5: Palliative Care & Pain Management).

Screening for Colorectal Neoplasms

Colorectal cancer is ideal for screening because it is a common disease that is fatal in almost 50% of cases yet is curable if detected at an earlier stage. Furthermore, most cases arise from benign adenomatous polyps that progress over many years to cancer, and removal of these polyps has been shown to prevent the majority of cancers. Colorectal cancer screening is endorsed by the US

Preventive Services Task Force, the Agency for Health Care Policy and Research, the American Cancer Society, and every professional gastroenterology and colorectal surgery society. Although there is continued debate about the optimal cost-effective means of providing population screening, there is unanimous consent that screening *of some kind* should be offered to every patient over the age of 50 years. Several analyses suggest that screening is cost effective.

It is important for primary care providers to understand the relative merits of various options and to discuss them with their patients. Despite growing awareness of the importance of screening on the part of medical professionals and the public, less than 50% of patients have undergone screening of any kind. Discussion and encouragement by the primary care provider are the most important factors in achieving patient compliance with screening programs. The potential for harm from screening must be weighed against the likelihood of benefit, especially in elderly patients with comorbid illnesses and shorter life expectancy.

Recommendations for screening from the US Multisociety Task Force are listed in Table 39–5. Patients with first-degree relatives with colorectal neoplasms (cancer or adenomatous polyps) are at increased risk; earlier and more frequent screening is recommended (preferably with colonoscopy) for these individuals. Recommendations for screening in families with inherited cancer syndromes or inflammatory bowel disease are provided in Chapter 15: Gastrointestinal Disorders. For patients at average risk for colorectal cancer, the recommendations of the Task Force are discussed below. Screening tests may be classified into two broad categories: stool-based tests and exams that visualize the structure of the colon by direct endoscopic inspection or radiographic imaging.

Table 39–5. Recommendations for colorectal cancer screening.[1]
Average-risk individuals 50 years old[2]
Annual fecal occult blood testing
Flexible sigmoidoscopy every 5 years
Annual fecal occult blood testing and flexible sigmoidoscopy every 5 years
Colonoscopy every 10 years
Barium enema every 5 years
Individuals with a family history of a first-degree member with colorectal neoplasia[3]
Single first-degree relative with colorectal cancer diagnosed at age 60 years: Begin screening at age

40. Screening guidelines same as average-risk individual; however, preferred method is colonoscopy every 10 years.
Single first-degree relative with colorectal cancer diagnosed at age < 60 years, or multiple first-degree relatives: Begin screening at age 40 or at age 10 years younger than age at diagnosis of the youngest affected relative, whichever is first in time. Recommended screening: colonoscopy every 5 years.

Stool-based Tests

Fecal occult blood test

Most colorectal cancers and some large adenomas result in increased chronic blood loss. A variety of tests for fecal occult blood are commercially available that have varying sensitivities and specificities for colorectal neoplasia. These include guaiac-based tests (Hemoccult I and II and Hemeoccult SENSA) that detect the pseudoperoxidase activity of heme or hemoglobin and fecal immunochemical tests (FITs) that detect human globin.

Guaiac-based tests have undergone the most extensive testing and currently have the greatest clinical use. For optimal detection, one specimen card must be prepared from three consecutive bowel movements. To reduce the likelihood of false-positive tests, patients should abstain from aspirin (in doses greater than 325 mg/d), NSAIDs, red meat, poultry, fish, and vegetables with peroxide activity (turnips, horseradish) for 72 hours. Vitamin C may cause a false-negative test. Slides should be developed within 7 days after preparation. The reported sensitivities of a single guaiac-based test for detection of colorectal cancer vary widely, but are lower for Hemeoccult II (35%) than Hemeoccult SENSA (65%). When fecal occult blood test is administered to the general population as part of a screening program, 2–6% of tests are positive. Of those with positive tests, 5–18% have colorectal cancer that is more likely to be at an earlier stage (stage I or II).

Several FITs are commercially available. These tests are highly specific for detecting human globin and therefore eliminate the need for pretest dietary restrictions. As with guaiac-based tests, sampling of three consecutive bowel movements is recommended. In clinical trials that compare FIT with guaiac-based tests, FIT had at least comparable sensitivity to Hemeoccult SENSA for detection of cancers (60–85%) with higher specificity. Because FITs are not affected by diet or medications and have superior accuracy, they are increasingly being substituted for guaiac-based tests despite a higher cost per test ($10-20).

The US Multi-Society Task Force emphasizes that colon cancer prevention should be the primary goal of screening. For that reason, the lower sensitivity of fecal occult blood tests for advanced neoplasia (cancer and advanced adenomatous polyps) makes them a less attractive choice for population-based screening than endoscopic or radiographic tests. Currently, fecal occult blood tests are most suitable in settings where health care resources are limited or in patients who desire a noninvasive method of screening. The Task Force recommends that tests with higher sensitivity for colorectal cancer (Hemeoccult SENSA or FIT) be used rather than less sensitive tests (Hemeoccult II). Regardless of which stool-based test is used, patients should understand that annual testing is required to achieve the maximum screening benefit and that a positive test will require evaluation by colonoscopy accompanied by removal of any polyps identified. If colonoscopy reveals no colorectal neoplasm, further screening for colorectal cancer can be deferred for 10 years. In a meta-analysis of four large, prospective, longitudinal studies, annual or biennial screening with Hemeoccult or Hemeoccult II reduced mortality from colorectal cancer by 25% among those who were compliant with regular testing. Long-term studies with more sensitive stool tests (Heme SENSA or FIT) have not been performed.

Multitarget DNA assay

A fecal DNA assay (Pre-Gen Plus) is available for screening for colorectal neoplasia. The test analyzes fecal DNA for 22 gene mutations and DNA integrity. The commercially available first-generation fecal DNA panel detected only one-half of cancers; however, a second-generation assay detected almost 90%. Although the Multisociety Task Force concluded that fecal DNA is an acceptable option for colorectal cancer screening, this test is not yet practical for population-based screening due to its high cost and cumbersome requirements for stool collection and mailing.

Endoscopic Examinations of the Colon

Flexible sigmoidoscopy

Use of a 60-cm flexible sigmoidoscope permits visualization of the rectosigmoid and descending colon. It requires no sedation and in many centers is performed by a nurse specialist or physician's assistant. Adenomatous polyps are identified in 10–20% and colorectal cancers in 1% of patients. (For management of adenomatous polyps identified at sigmoidoscopy, see Chapter 15: Gastrointestinal Disorders.) Case-control studies suggest that screening sigmoidoscopy programs lead to a 60% reduction in colorectal cancer mortality. The risk of serious complications (perforation) associated with flexible sigmoidoscopy is less than 1:10,000 patients.

The chief disadvantage of screening with flexible sigmoidoscopy is that is does not examine the proximal colon. The prevalence of proximal versus distal neoplasia is higher in people over age 65 years of age, African Americans, and women. In men, approximately 50% of advanced neoplasms (cancer, adenomas 1 cm in size, polyps with villous histology, or high-grade dysplasia) are located in the proximal colon, compared with 60–70% in women. The finding at sigmoidoscopy of an adenomatous polyp in the distal colon increases the likelihood at least twofold that an advanced neoplasm is present in the proximal colon. Therefore, patients found on screening sigmoidoscopy to have an adenomatous polyp of any size should subsequently undergo colonoscopy to evaluate the proximal colon. Using this strategy in men, it is estimated that screening sigmoidoscopy programs will detect approximately 65% of advanced colonic neoplasms. In women, however, sigmoidoscopy screening programs may fail to detect up to 65% of advanced neoplasia.

Colonoscopy

Colonoscopy permits examination of the entire colon. In addition to detecting early cancers, colonoscopy allows removal of adenomatous polyps by biopsy or polypectomy, which is believed to reduce the risk of subsequent cancer. Over the past decade, there has been a dramatic increase in screening colonoscopy and a similar decrease in screening sigmoidoscopy due to poor reimbursement and the perceived inferiority of sigmoidoscopy compared with colonoscopy. Colonoscopy requires aggressive bowel cleansing prior to the examination. To alleviate discomfort, intravenous sedation is used for most patients. The incidence of serious complications after colonoscopy (perforation, bleeding, cardiopulmonary events) is 0.1%. In asymptomatic individuals between 50 and 75 years of age undergoing screening colonoscopy, the prevalence of advanced neoplasia is 4–11% and of cancer is 0.1–1%.

Although colonoscopy is believed to be the most sensitive test for detecting adenomas and cancer, it is not infallible. In several studies, the rate of colorectal cancer within 3 years of a screening colonoscopy was 0.7–0.9%, ie, approximately 1 in 110 patients. This may be attributable to adenomatous polyps and early cancers that were overlooked during colonoscopy. Studies of back-to-back colonoscopies confirm that endoscopists overlook 6–12% of polyps > 1 cm and up to 25% of smaller adenomas. Polyps that are small, flat, or located behind folds are easily missed, especially if the bowel preparation is poor. Population-based case-control and cohort studies suggest that colonoscopy is associated with greater reduction in colorectal cancer incidence and mortality in the distal colon than the proximal colon. This may be attributable to incomplete examination of the proximal colon, and differences between the proximal and distal colon that include worse bowel preparation, more aggressive polyp biology, or a higher prevalence of flat polyps. The latter are more common that previously recognized, are more likely to contain advanced pathology, and are more difficult to identify than raised (sessile or pedunculated) polyps. To optimize diagnostic accuracy as well as patient safety and comfort, colonoscopy should be performed after optimal bowel preparation by a well-trained endoscopist who spends sufficient time (at least 7 minutes) carefully examining the colon (especially the proximal colon) while withdrawing the endoscope.

Radiographic Examinations of the Colon

CT colonography

Using helical CT with computer-assisted image reconstruction, two- and three-dimensional views can be generated of the colon lumen that simulate the view of colonoscopy. CT colonography requires a similar bowel cleansing regimen as colonoscopy as well as insufflation of air into the colon through a rectal tube, which may be associated with discomfort. Nonetheless, this examination is performed rapidly and requires no sedation or intravenous contrast. It has minimal acute risk although there is controversy about potential long-term risks related to radiation exposure from CT examinations. Several large studies have compared the accuracy of virtual colonoscopy with colonoscopy for colorectal screening. Using current imaging software with multidetector helical scanners, the sensitivity is > 95% for the detection of cancer and > 84–92% for the detection of polyps 10 mm in size. The sensitivity for polyps 6–9 mm in size ranges from 57% to 84%; for polyps 5 mm or less, the sensitivity is extremely poor.

Patients undergoing screening with CT colonography should be managed appropriately. If no polyps are found, the interval for repeat screening examination is uncertain; however, 5 years may be reasonable. All patients with polyps 10 mm in size should be referred for colonoscopy with polypectomy because of the high prevalence (30%) of advanced pathology (cancer, high-grade dysplasia, or villous features) within these polyps. The optimal management of patients with polyps < 10 mm in size is controversial. The likelihood of advanced pathology in polyps 6–9 mm in size is 4–7% and in polyps 1–5 mm is < 2%. Studies are ongoing to determine the natural history of polyps within this size range. Pending this information, the US Multisociety Task Force currently recommends that colonoscopy with polypectomy be offered to patients with one or more 6–9 mm polyps. Patients who refuse or who have increased risk of carcinoma should undergo surveillance CT colonography in 3–5 years. At the present time, there is no consensus on the management of patients with polyps < 6 mm; however, some radiologists choose not even to report these findings.

Barium enema

Double-contrast barium enema was previously an attractive screening technique because it was widely available, relatively inexpensive, and safe. However, compared to CT colonography, it is more time consuming and difficult to perform, less comfortable, and less accurate. Although it continues to be included among recommended screening options, it has been supplanted CT colonography, where available. A multicenter trial demonstrated that the sensitivity of barium enema is only 50% for polyps 1 cm and 55–85% for early-stage cancers when compared with colonoscopy. At present, barium enema may be recommended when screening of the entire colon is desired but expertise in CT colonography is unavailable and the patient is unable or unwilling to undergo colonoscopy.

When to Refer

- Patients with symptoms (change in bowel habits, hematochezia), signs (mass on abdominal examination or digital rectal examination [DRE]), or laboratory tests (iron deficiency anemia) suggestive of colorectal neoplasia should be referred for colonoscopy.
- Patients with suspected cancer or adenomatous polyps of any size should be referred for colonoscopy.
- Virtually all patients with proven colorectal cancer should be referred to a surgeon for resection. Patients with stage III or IV disease should be referred to an oncologist.

When to Admit

- Patients with complications of colorectal cancer (obstruction, acute bleeding) requiring urgent evaluation and intervention.
- Patients with severe complications of chemotherapy.
- Patients with advanced metastatic disease requiring palliative care.

Carcinoma of the Anus

The anal canal is lined from its proximal to distal extent by columnar, transitional and non-keratinized squamous epithelium, which merges at the anal verge with the keratinized perianal skin. Tumors arising from the mucosa of the anal canal are relatively rare, comprising only 1–2% of all cancers of the anus and large intestine. Squamous cancers make up the majority of anal cancers. Anal cancer is increased among people practicing receptive anal intercourse and those with a history of anorectal warts. In over 80% of cases, HPV may be detected, suggesting that this virus is a major causal factor. Anal cancer is increased in HIV-infected individuals, possibly due to interaction with HPV. Bleeding, pain, and local tumor are the most common symptoms. The lesion is often confused with hemorrhoids or other common anal disorders. These tumors tend to become annular, invade the sphincter, and spread upward via the lymphatics into the perirectal mesenteric lymphatic nodes. MR scan and endoluminal ultrasound assist in determining the depth of penetration and local spread.

Treatment depends on the tumor location and histologic stage. Small (< 3 cm) superficial lesions of the perianal skin may be treated with wide local excision. Adenocarcinoma of the anal canal is treated in similar fashion to rectal cancer (see above), commonly by abdominoperineal resection with adjuvant or neoadjuvant chemoradiotherapy. Squamous cancer of the anal canal and large perianal tumors invading the sphincter or rectum are treated with combined-modality therapy that includes external radiation with simultaneous chemotherapy (fluorouracil and either mitomycin or cisplatin). Local control is achieved in 80% of patients. Radical surgery (abdominoperineal resection) is reserved for patients who fail chemotherapy and radiation therapy. The 5-year survival rate is 60–70% for localized tumors and over 25% for metastatic (stage IV) disease.

Prostate Cancer

Maxwell V. Meng, MD, FACS

Essentials of Diagnosis

- Prostatic induration on DRE or elevation of PSA.
- Most often asymptomatic.
- Rarely: systemic symptoms (weight loss, bone pain).

General Considerations

Prostatic cancer is the most common noncutaneous cancer detected in American men and the second leading cause of cancer-related death. In the United States, over 218,000 new cases of prostate cancer are diagnosed annually, and about 27,000 deaths result. However, the clinical incidence of the disease does not match the prevalence noted at autopsy, where more than 40% of men over 50 years of age are found to have prostatic carcinoma. Most such occult cancers are small and contained within the prostate gland. Few are associated with regional or distant disease. The incidence of prostatic cancer increases with age. Whereas 30% of men aged 60–69 years will have the disease, autopsy incidence increases to 67% in men aged 80–89 years. Although the global prevalence of prostatic cancer at autopsy is relatively consistent, the clinical incidence varies considerably (high in North America and European countries, intermediate in South America, and low in the Far East), suggesting that environmental or dietary differences among populations may be important for prostatic cancer growth. A 50-year-old American man has a lifetime risk of 40% for latent cancer, 16% for developing clinically apparent cancer, and a 2.9% risk of death due to prostatic cancer. Blacks, men with a family history of prostatic cancer, and those with a history of high dietary fat intake are at increased risk for developing prostate cancer.

Clinical Findings

Symptoms and Signs

Prostate cancer may manifest as focal nodules or areas of induration within the prostate at the time of DRE. However, currently most prostate cancers are associated with palpably normal prostates and are detected on the basis of elevations in serum PSA.

Patients rarely present with signs of urinary retention or neurologic symptoms as a result of epidural metastases and cord compression. Obstructive voiding symptoms are most often due to benign prostatic hyperplasia, which occurs in the same age group. Nevertheless, large or locally extensive prostatic cancers can cause obstructive voiding symptoms while lymph node metastases can lead to lower extremity lymphedema. As the axial skeleton is the most common site of metastases, patients may present with back pain or pathologic fractures.

Laboratory Findings

Serum tumor markers

PSA is a glycoprotein produced only by cells, either benign or malignant, of the prostate gland. The serum level is typically low and correlates with the volume of both benign and malignant prostate tissue. Measurement of serum PSA is useful in detecting and staging prostate cancer, monitoring response to treatment, and detecting recurrence before it becomes clinically evident. As a screening test, PSA will be elevated in 10–15% of men. Approximately 18–30% of men with intermediate degrees of elevation (4.1–10 ng/mL) will be found to have prostate cancer. Between 50% and 70% of those with elevations greater than 10 ng/mL will have prostate cancer. (See age-specific PSA reference ranges under Screening for Prostate Cancer, below.) Patients with intermediate levels of PSA usually have localized and therefore potentially curable cancers. It should be remembered that approximately 20% of patients who undergo radical prostatectomy for localized prostate cancer have normal levels of PSA.

In untreated patients with prostate cancer, the level of PSA correlates with the volume and stage of the disease. Whereas most organ-confined cancers are associated with PSA levels less than 10 ng/mL, advanced disease (seminal vesicle invasion, lymph node involvement, or occult distant metastases) is more common in patients with PSA levels in excess of 40 ng/mL. Approximately 98% of patients with metastatic prostate cancer will have elevated PSA. However, there are rare cancers that are localized despite substantial elevations in PSA. Therefore, initial treatment decisions cannot be made on the basis of PSA testing alone. A rising PSA after therapy is usually consistent with progressive disease, either locally recurrent or metastatic.

Miscellaneous laboratory testing

Patients in urinary retention or those with ureteral obstruction due to loco-regionally advanced prostate cancers may present with elevations in blood urea nitrogen or creatinine. Patients with bony metastases may have elevations in alkaline phosphatase or hypercalcemia. Laboratory and clinical evidence of disseminated intravascular coagulation can occur in patients with advanced prostate cancers.

Prostate biopsy

Transrectal ultrasound-guided biopsy is the standard method for detection of prostate cancer. The use of a spring-loaded, 18-gauge biopsy needle has allowed transrectal biopsy to be performed with little patient discomfort and minimal morbidity. Local anesthesia is routinely used and increases the tolerability of the procedure. The specimen preserves glandular architecture and permits accurate grading. Prostate biopsy specimens are taken from the apex, mid-portion, and base in men who have an abnormal DRE or an elevated serum PSA, or both. Extended-pattern biopsies, including a total of at least ten biopsies, are associated with improved cancer detection and risk stratification of patients with newly diagnosed disease. Patients with abnormalities of the seminal vesicles can have these structures specifically biopsied to identify local tumor invasion.

Imaging

Transrectal ultrasonography has been used largely for the staging of prostate carcinomas, where they typically appear as hypoechoic areas. In addition, transrectal ultrasound-guided, rather than digitally guided, biopsy of the prostate is a more accurate way to evaluate suspicious lesions. Use of imaging should be tailored to the likelihood of advanced disease in newly diagnosed cases. Asymptomatic patients with well-differentiated to moderately differentiated cancers, thought to be localized to the prostate on DRE and transurethral ultrasound and associated with modest elevations of PSA (ie, < 10 ng/mL), need no further imaging.

MRI of the prostate allows for evaluation of the prostate lesion as well as regional lymph nodes. The positive predictive value for detection of both capsular penetration and seminal vesicle invasion is similar for transrectal ultrasound and MRI. CT plays little role because of its inability to accurately identify or stage prostate cancers, but it can be used to detect regional lymphatic metastases and intra-abdominal metastases.

Radionuclide bone scan is superior to conventional plain skeletal radiographs in detecting bony metastases. Most prostate cancer metastases are multiple and most commonly localized to the axial skeleton. Those men with more advanced local lesions, symptoms of metastases (eg, bone pain), high-grade disease, or elevations in PSA greater than 20 ng/mL should undergo radionuclide bone scan. Because of the high frequency of abnormal scans in patients in this age group resulting from degenerative joint disease, plain films are often necessary in evaluating patients with indeterminate findings on bone scan. Cross-sectional imaging either by CT or MRI is usually indicated only in those patients in the latter group who have negative bone scans in an attempt to detect lymph node metastases. Patients found to have enlarged pelvic lymph nodes are candidates for FNA.

Intravenous urography and cystoscopy are not routinely needed to evaluate patients with prostate cancer.

Despite application of modern, sophisticated techniques, understaging of prostate cancer occurs in at least 20% of patients.

Screening for Prostate Cancer

Whether screening for prostate cancer results in a decrease in yearly mortality rates due to the disease is the subject of much debate. The screening tests currently available include DRE, PSA testing, and transrectal ultrasound. Depending on the patient population being evaluated, detection rates using DRE alone vary from 1.5% to 7%. Unfortunately, most cancers detected in this manner are advanced (stage T3 or greater). Transrectal ultrasound should not be used as a first-line screening tool because of its expense, low specificity (and therefore high biopsy rate), and minimal improvement in detection rate when compared with the combined use of DRE and PSA testing.

PSA testing increases the detection rate of prostate cancers compared with DRE. Approximately 2–2.5% of men older than 50 years of age will be found to have prostate cancer using PSA testing compared with a rate of approximately 1.5% using DRE alone. PSA is not specific for cancer, and there is considerable overlap of values between men with benign prostate hyperplasia and those with prostate cancers. The sensitivity, specificity, and positive predictive value of PSA and DRE are listed in Table 39–6. PSA-detected cancers are more likely to be localized compared with those detected by DRE alone.

Table 39–6. Screening for prostatic cancer: Test performance.

Test	**Sensitivity**	**Specificity**	**Positive Predictive Value**
Abnormal PSA (> 4 ng/mL)	0.67	0.97	0.43
Abnormal DRE	0.50	0.94	0.24
Abnormal PSA or DRE	0.84	0.92	0.28
Abnormal PSA *and* DRE	0.34	0.995	0.49

DRE, digital rectal examination; PSA, prostate-specific antigen.

Modified, with permission, from Kramer BS et al.

Prostate cancer screening: what we know and what we need to know. Ann Intern Med. 1993 Nov 1;119(9):914–23.

To improve the performance of PSA as a screening test, several investigators have developed alternative methods for its use. The serial measurement of PSA over time (PSA velocity) may increase specificity for cancer detection with little loss in sensitivity. A rate of change in PSA greater than 0.75 ng/mL per year is associated with an increased likelihood of cancer detection. In a patient with a normal DRE, an elevated PSA, and a normal transrectal ultrasound, the indications for prostate biopsy may be refined by calculating PSA density (serum PSA/volume of the prostate as measured by ultrasound). Patients with high PSA density are more likely to have disease despite a normal DRE and normal transrectal ultrasound. Some have found measurement of PSA transition zone density (portion of the prostate that enlarges with development of benign prostate hyperplasia) to be more predictive of the presence or absence of cancer than PSA density calculated using the entire prostate volume. As PSA concentration is directly related to patient age, establishment of age-specific reference ranges increases specificity (fewer older men with benign prostate hyperplasia would undergo evaluation) and increases sensitivity (more younger men with cancer would undergo evaluation). Age-specific reference ranges have been established: men 40–49, < 2.5 ng/mL; men 50–59, < 3.5 ng/mL; men 60–69, < 4.5 ng/mL; and men 70–79, < 6.5 ng/mL (based on a previously normal serum PSA of < 4 ng/mL). Black men have lower age-specific reference ranges (age 40–49, < 2 ng/mL; age 50–59, < 4 ng/mL; age 60–69, < 4.5 ng/mL; age 70–79, < 5.5 ng/mL). A more recent attempt at refining PSA has been the measurement of free serum and protein-bound levels (cancer patients have a lower percentage of free serum PSA). Generally, men with free fractions exceeding 25% are unlikely to have prostate cancer, whereas those with free fractions less than 10% have an approximately 50% chance of having prostate cancer. Early reports using cutoffs of 18–20% of free PSA resulted in 5–10% lost sensitivity for 15–40% gains in specificity. The frequency of PSA testing remains a matter of some debate. In men with a normal DRE and a PSA > 2.5 ng/mL, PSA testing should be performed yearly because approximately 50% of these patients convert to having a PSA > 4 ng/mL. Screening can be performed biennially in those with a normal DRE and serum PSA < 2.5 ng/mL; progression in this group is less likely.

Staging

The majority of prostate cancers are adenocarcinomas. Most arise in the periphery of the prostate (peripheral zone), though a small percentage arise in the central (5–10%) and transition zones (20%) of the gland. Pathologists utilize the Gleason grading system whereby a "primary" grade is applied to the architectural pattern of malignant glands occupying the largest area of the specimen and a "secondary" pattern is assigned to the next largest area of cancer. Grading is based on architectural rather than histologic criteria, and five "grades" are possible. Adding the score of the primary and secondary patterns gives a Gleason score. Grade correlates with tumor volume, pathologic stage, and prognosis.The TNM classification is shown in eTable 39–6.1.

eTable 39–6.1. TNM staging system for prostate cancer.	
T: Primary tumor	
Tx	Cannot be assessed
T0	No evidence of primary tumor
T1a	Carcinoma in 5% or less of tissue resected; normal DRE
T1b	Carcinoma in more than 5% of tissue resected; normal DRE
T1c	Detected from elevated PSA alone; normal DRE
T2a	Tumor in $^{1}/_{2}$ of one lobe

T2b	Tumor in >$^1/_2$ of one lobe
T2c	Tumor in both lobes
T3a	Extracapsular extension
T3b	Seminal vesicle involvement
T4	Adjacent organ involvement
N: Regional lymph nodes	
Nx	Cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in one or more regional lymph nodes
M: Distant metastasis	
Mx	Cannot be assessed
M0	No distant metastasis
M1a	Metastasis to nonregional lymph node(s)
M1b	Metastasis to bone(s)
M1c	Metastasis to other site(s) with or without bone disease

DRE, digital rectal examination; PSA, prostate-specific antigen.

Treatment

Localized Disease

The optimal treatment for patients with clinically localized prostate cancers remains controversial. Patients need to be advised of all treatment options, including active surveillance, with the specific benefits, risks, and limitations. Currently, treatment decisions are made based on tumor grade and stage as well as the age and health of the patient. Although selected patients may be candidates for surveillance based on age or health and evidence of small-volume or well-differentiated cancers, most men with an anticipated life expectancy in excess of 10 years should be considered for treatment. Both radiation therapy and radical prostatectomy result in acceptable levels of local control. A large, prospective, randomized trial compared surveillance with radical prostatectomy in 695 men with clinically localized and well- differentiated to moderately differentiated tumors for a median of 8.2 years. Radical prostatectomy reduced disease-specific mortality, overall mortality, and risks of metastasis and local progression. The absolute reduction in the risk of death after 10 years was small yet statistically significant, but the reductions in the risk of metastasis and local tumor progression were substantial. This trial accrued patients in Sweden between 1989 and 1999, thus likely including patients with greater cancer burden compared with that in patients currently diagnosed using PSA screening.

Radical Prostatectomy

During radical prostatectomy, the seminal vesicles, prostate, and ampullae of the vas deferens are removed. Refinements in technique have allowed preservation of urinary continence in most patients and erectile function in selected patients. Radical prostatectomy can be performed via open retropubic, transperineal, or laparoscopic (with or without robotic assistance) surgery. Local recurrence is uncommon after radical prostatectomy, and the incidence is related to pathologic stage. Organ-confined cancers rarely recur; however, cancers with adverse pathologic features (capsular penetration, seminal vesicle invasion) are associated with higher local (10–25%) and distant (20–50%) relapse rates.

Ideal candidates for prostatectomy include healthy patients with stages T1 and T2 prostate cancers. Patients with advanced local tumors (T4) or lymph node metastases are rarely candidates for prostatectomy alone, although surgery is sometimes used in combination with hormonal therapy and postoperative radiation therapy for select high-risk patients.

Patients with advanced pathologic stage or positive surgical margins are at an increased risk for local and distant tumor relapse. Such patients are candidates for adjuvant therapy (radiation for positive margins or androgen deprivation for lymph node metastases). Although adjuvant radiation appears to reduce local recurrences (0–5% with radiation versus 15–30% without), it has little or no impact on distant failure rates (30–35% with radiation versus 30–45% without). Recent evidence suggests that salvage radiotherapy after radical prostatectomy, within 2 years of PSA relapse, increases prostate cancer-specific survival in men with shorter PSA doubling time (< 6 months).

Radiation Therapy

Radiation can be delivered by a variety of techniques including use of external beam radiotherapy and transperineal implantation of radioisotopes. Morbidity is limited, and the survival of patients with localized cancers (T1, T2, and selected T3) approaches 65% at 10 years. As with surgery, the likelihood of local failure correlates with technique and tumor characteristics. The likelihood of a positive prostate biopsy more than 18 months after radiation varies between 20% and 60%. Patients with local recurrence are at an increased risk of cancer progression and cancer death compared with those who have negative biopsies. Ambiguous target definitions, inadequate radiation doses, and understaging of the tumor may be responsible for the failure noted in some series.

Newer techniques of radiation (implantation, conformal therapy using three-dimensional reconstruction of CT-based tumor volumes, heavy particle, charged particle, and heavy charged particle) may improve local control rates. Three-dimensional conformal radiation delivers a higher dose because of improved targeting and appears to be associated with greater efficacy as well as lower likelihood of adverse side effects compared with previous techniques. As a result of improvements in imaging, most notably transrectal ultrasound, there has been a resurgence of interest in brachytherapy—the implantation of permanent or temporary radioactive sources (palladium, iodine, or iridium) into the prostate. Brachytherapy can be combined with external beam radiation in patients with higher-grade or higher-volume disease or as monotherapy in those with low-grade or low-volume malignancies. The PSA may rise after brachytherapy because of prostate inflammation and necrosis. This transient elevation (PSA bounce) should not be mistaken for recurrence and may occur up to 20 months after treatment.

Surveillance

A beneficial impact of treating localized prostate cancer with respect to survival has not been conclusively demonstrated. Therefore, surveillance alone may be an appropriate form of management for selected patients with prostate cancer. Patients included in observational series are typically older with small volume, well-differentiated cancers. Currently, many men diagnosed with prostate cancer may be candidates for surveillance due to the significant migration to lower stage, as well lower grade, resulting from screening for prostate cancer using PSA testing. Depending on the age and health of the patient, some of these very low-volume, low-grade cancers may never become clinically relevant and can be monitored with serial PSA levels, rectal examinations, and periodic prostate biopsies to assess grade and extent of tumor. The goal of surveillance is to avoid treatment in men who never experience disease progression while recognizing and effectively treating men with early evidence of progression. End points for intervention in patients on surveillance have not been clearly defined and surveillance regimens remain investigational.

Cryosurgery

Cryosurgery is a technique whereby liquid nitrogen is circulated through small hollow-core needles inserted into the prostate under ultrasound guidance. The freezing process results in tissue destruction. There has been a resurgence of interest in less invasive forms of therapy for localized prostate cancer as well as several recent technical innovations, including improved percutaneous techniques, expertise in transrectal ultrasound, improved cryotechnology, and better understanding of cryobiology.

The positive biopsy rate after cryoablation ranges between 7% and 23%.

Locally and Regionally Advanced Disease

Prostate cancers associated with minimal degrees of capsular penetration are candidates for standard irradiation or surgery. Those with locally extensive cancers, including those with seminal vesicle and bladder neck invasion, are at increased risk for both local and distant relapse despite conventional therapy. Currently, a variety of investigational regimens are being tested in an effort to improve cancer outcomes in such patients. Combination therapy (androgen deprivation combined with surgery or irradiation), newer forms of irradiation, and hormonal therapy alone are being tested, as is neoadjuvant and adjuvant chemotherapy. Neoadjuvant and adjuvant androgen deprivation therapy combined with external beam radiation therapy have demonstrated improved survival compared with external beam radiation therapy alone.

Metastatic Disease

Since death due to prostate carcinoma is almost invariably the result of failure to control metastatic disease, research has emphasized efforts to improve control of distant disease. It is well known that most prostate carcinomas are hormone dependent and approximately 70–80% of men with metastatic prostate carcinoma will respond to various forms of androgen deprivation. Androgen deprivation may be affected at several levels along the pituitary–gonadal axis using a variety of methods or agents (Table 39–7). Use of luteinizing hormone-releasing hormone (LHRH) agonists (leuprolide, goserelin) achieves androgen deprivation without orchiectomy or administration of diethylstilbestrol and is currently the most common method of reducing testosterone levels. Because of its rapid onset of action, ketoconazole should be considered in patients with advanced prostate cancer who present with spinal cord compression, bilateral ureteral obstruction, or disseminated intravascular coagulation. Although testosterone is the major circulating androgen, the adrenal gland secretes the androgens dehydroepiandrosterone, dehydroepiandrosterone sulfate, and androstenedione. Some investigators believe that suppressing both testicular and adrenal androgens allows for a better initial and longer response than methods that only inhibit production of testicular androgens. Complete androgen blockade can be achieved by combining an antiandrogen with use of an LHRH agonist or orchiectomy. Nonsteroidal antiandrogen agents appear to act by competitively binding the receptor for DHT, the intracellular androgen responsible for prostate cell growth and development. A meta-analysis of trials comparing the use of either an LHRH agonist or orchiectomy alone with the use of either in combination with an antiandrogen agent shows little benefit of combination therapy. However, patients at risk for disease-related symptoms (bone pain, obstructive voiding symptoms) due to the initial elevation of serum testosterone that accompanies the use of an LHRH agonist should receive antiandrogens initially. Bisphosphonates are increasingly being used to prevent osteoporosis associated with androgen deprivation, to decrease bone pain from metastases, and to reduce skeletal related events.

Table 39–7. Androgen deprivation for prostatic cancer.

Level	**Agent**	**Dose**	**Sequelae**
Pituitary, hypothalamus	Diethylstibestrol	1–3 mg orally daily	Gynecomastia, hot flushes, thromboembolic disease, erectile dysfunction
	LHRH agonists	Monthly or 3-monthly depot injection	Erectile dysfunction, hot flushes, gynecomastia, rarely anemia

Adrenal	Ketoconazole	400 mg three times orally daily	Adrenal insufficiency, nausea, rash, ataxia
	Aminoglutethimide	250 mg four times orally daily	Adrenal insufficiency, nausea, rash, ataxia
	Corticosteroids	Prednisone: 20–40 mg orally daily	Gastrointestinal bleeding, fluid retention
Testis	Orchiectomy		Gynecomastia, hot flushes, erectile dysfunction
Prostate cell	Antiandrogens	Flutamide: 250 mg three times orally dailyBicalutamide: 50 mg orally daily	No erectile dysfunction when used alone; nausea, diarrhea

LHRH, luteinizing-hormone-releasing hormone.

Docetaxel is the first cytotoxic chemotherapy agent to improve survival in patients with hormone-refractory prostate cancer. Current research is underway combining docetaxel with androgen deprivation therapy, radiation therapy, and surgery to determine whether combinations are effective in patients with high-risk prostate cancer. Immune therapies are also under investigation and have shown promise for patients with advanced prostate cancer.

Prognosis

The likelihood of success of surveillance or treatment can be predicted using risk assessment tools that usually combine stage, grade, PSA level, and number and extent of positive prostate biopsies. Several tools are available on the Internet (eg, http://mskcc.org/mskcc/html/5794.cfm). One of the most widely used is the Kattan nomogram; it incorporates tumor stage, grade, and PSA level to predict the likelihood that a patient will be disease-free after radical prostatectomy or radiation therapy.

The CAPRA nomogram uses serum PSA, Gleason grade, clinical stage, percent positive biopsies, and patient age in a point system to risk stratify and predict the likelihood of PSA recurrence 3 and 5 years after radical prostatectomy (Tables 39–8 and 39–9). The CAPRA has been validated on large multicenter and international radical prostatectomy cohorts.

Table 39–8. The UCSF Cancer of the Prostate Risk Assessment (CAPRA).

Variable	**Level**	**Points**
PSA (ng/mL)	0–6	0
	6.1–10	1
	10.1–20	2
	20.1–30	3
	> 30	4
Gleason grade	1–3/1–3	0
	1–3/4–5	1
	4–5/1–5	3
T-stage	T1 or T2	0
	T3a	1
% positive biopsies (biopsy cores positive divided by the number of	< 34%	0

biopsies obtained)		
	> 34%	1
Age	< 50 years	0
	> 50 years	1

Table 39–9. CAPRA: Probability of freedom from PSA recurrence after radical prostatectomy by CAPRA point total.

CAPRA Score	**3-Year Recurrence Free Survival (%) (95% CI)**	**5-Year Recurrence Free Survival (%) (95% CI)**
0–1	91 (85–95)	85 (73–92)
2	89 (83–94)	81 (69–89)
3	81 (73–87)	66 (54–76)
4	81 (69–89)	59 (40–74)
5	69 (51–82)	60 (37–77)
6	54 (27–75)	34 (12–57)
7+	24 (9–43)	8 (0–28)

PSA, prostate-specific antigen.

The patterns of prostate cancer progression have been well defined. Small and well-differentiated cancers (grades 1 and 2) are usually confined within the prostate, whereas large-volume (> 4 mL) or poorly differentiated (grades 4 and 5) cancers are more often locally extensive or metastatic to regional lymph nodes or bone. Penetration of the prostate capsule by cancer is common and occurs along perineural spaces. Seminal vesicle invasion is associated with a high likelihood of regional or distant disease, and disease recurrence. Lymphatic metastases can be identified in the obturator and internal iliac lymph node chains. The axial skeleton, as mentioned previously, is the most common site of distant metastases.

When to Refer

- All patients should be referred to an urologist. PSA remains integral in prostate cancer diagnosis. Low-risk disease may be managed by active surveillance, surgery, or radiation therapy.
- High-risk disease often requires multimodal treatment strategies.

Bladder Cancer

Essentials of Diagnosis

- Irritative voiding symptoms.
- Gross or microscopic hematuria.
- Positive urinary cytology in most patients.
- Filling defect within bladder noted on imaging.

General Considerations

Bladder cancer is the second most common urologic cancer; it occurs more commonly in men than women (2.7:1), and the mean age of patients at diagnosis is 65 years. Cigarette smoking and exposure to industrial dyes or solvents are risk factors for the disease and account for approximately 60% and 15% of new cases, respectively. Ninety-eight percent of primary bladder cancers are epithelial malignancies, with the majority being urothelial cell carcinomas (90%). Adenocarcinomas and squamous cell cancers account for approximately 2% and 7%, respectively, of all bladder cancers detected in the United States. The latter is often associated with schistosomiasis, vesical calculi, or prolonged catheter use.

Clinical Findings

Symptoms and Signs

Hematuria—gross or microscopic, chronic or intermittent—is the presenting symptom in 85–90% of patients with bladder cancer. Irritative voiding symptoms (urinary frequency and urgency) occur in a small percentage of patients as a result of the location or size of the cancer. Most patients with bladder cancer do not have signs of the disease because of its superficial nature. Abdominal masses detected on bimanual examination may be present in patients with large-volume or deeply infiltrating cancers. Hepatomegaly or palpable lymphadenopathy may be present in patients with metastatic disease, and lymphedema of the lower extremities may be present as a result of locally advanced cancers or metastases to pelvic lymph nodes.

Laboratory Findings

Urinalysis reveals microscopic or gross hematuria in the majority of cases. On occasion, hematuria may be accompanied by pyuria. Azotemia may be present in a small number of cases associated with ureteral obstruction. Anemia may occasionally be due to chronic blood loss or to bone marrow metastases. Exfoliated cells from normal and abnormal urothelium can be readily detected in voided urine specimens. Cytology can be useful in detecting the disease at the time of initial presentation or to detect recurrence. Cytology is sensitive in detecting cancers of higher grade and stage (80–90%)

but less so in detecting superficial or well-differentiated lesions (50%). There are numerous urinary tumor markers under investigation for screening, assessing recurrence, progression, prognosis or response to therapy; the NMP22 point-of-care assay for a specific urinary protein has shown utility in detecting recurrent tumors.

Imaging

Bladder cancers may be identified using ultrasound, CT, or MRI where filling defects within the bladder are noted. However, the presence of cancer is confirmed by cystoscopy and biopsy, with imaging primarily used to evaluate the upper urinary tract and stage more advanced lesions.

Cystourethroscopy and Biopsy

The diagnosis and staging of bladder cancers are made by cystoscopy and transurethral resection. If cystoscopy—performed usually under local anesthesia—confirms the presence of bladder cancer, the patient is scheduled for transurethral resection under general or regional anesthesia. Random bladder and, on occasion, prostate urethral biopsies are performed to detect occult disease elsewhere in the bladder and potentially identify patients at greater risk for tumor recurrence and progression.

Pathology & Staging

Grading is based on cellular features: size, pleomorphism, mitotic rate, and hyperchromatism. Bladder cancer staging is based on the extent of bladder wall penetration and the presence of regional or distant metastases.The TNM classification of the American Joint Cancer Committee for bladder cancer is shown in eTable 39–9.1.

eTable 39–9.1. TNM staging system for bladder cancer

T: Primary tumor	
Tx	Cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ (CIS)
Ta	Noninvasive papillary carcinoma
T1	Invasion into lamina propria
T2a	Invasion into superficial layer of muscularis propria
T2b	Invasion into deep layer of muscularis propria
T3a	Microscopic invasion into perivesical tissue
T3b	Macroscopic invasion into perivesical tissue
T4a	Invasion into adjacent organs
T4b	Invasion into pelvic sidewall
N: Regional lymph nodes	
Nx	Cannot be assessed
N0	No regional lymph node metastasis

N1	Metastasis in a single lymph node 2 cm or less
N2	Metastasis in a single lymph node > 2 cm and < 5 cm or multiple nodes none > 5 cm
N3	Metastasis in lymph node > 5 cm
M: Distant metastasis	
Mx	Cannot be assessed
M0	No distant metastasis
M1	Distant metastasis present

AJCC Cancer Staging Manual, 6th ed. Springer, 2002.

The natural history of bladder cancer is based on two separate but related processes: tumor recurrence within the bladder and progression to higher-stage disease. Both are correlated with tumor grade and stage.

Treatment

Patients with superficial cancers (Ta, T1) are treated with complete transurethral resection and selective use of intravesical chemotherapy. In the subset of patients with large, high-grade, recurrent Ta lesions or T1 cancers and those with carcinoma in situ are good candidates for adjuvant intravesical therapy.

Patients with invasive (T2, T3) but still localized cancers are at risk for both nodal metastases and progression and require radical cystectomy, irradiation, or the combination of chemotherapy and selective surgery or irradiation due to the much higher risk of progression compared with patients with lower-stage lesions.

For patients with muscle invasive (T2 or greater) transitional cell carcinoma, neoadjuvant systemic chemotherapy prior to radical cystectomy is superior to radical cystectomy alone. This is particularly important for higher stage or bulky tumors in order to improve their surgical resectability.

Intravesical Chemotherapy

Immunotherapeutic or chemotherapeutic agents delivered directly into the bladder via a urethral catheter can reduce the likelihood of recurrence in those who have undergone complete transurethral resection. Most agents are administered weekly for 6–12 weeks. Efficacy may be increased by prolonging contact time to 2 hours. The use of maintenance therapy after the initial induction regimen is beneficial. Common agents include thiotepa, mitomycin, doxorubicin, and BCG, the last being the most effective agent when compared with the others with respect to reducing disease progression. Side effects of intravesical chemotherapy include irritative voiding symptoms and hemorrhagic cystitis. Patients in whom symptoms or infection develop from BCG may require antituberculous therapy.

Surgical Treatment

Although transurethral resection is the initial form of treatment for all bladder tumors since it is diagnostic, allows for proper staging, and controls superficial cancers, muscle-infiltrating cancers require more aggressive treatment. Partial cystectomy is indicated in selected patients with solitary lesions or those with cancers in a bladder diverticulum. Radical cystectomy entails removal of the bladder, prostate, seminal vesicles, and surrounding fat and peritoneal attachments in men and the uterus, cervix, urethra, anterior vaginal vault, and usually the ovaries in women. Bilateral pelvic lymph node dissection is performed in all patients.

Urinary diversion can be performed using a conduit of small or large bowel. However, continent forms of diversion have been developed that avoid the necessity of an external appliance and can be considered in a significant number of patients.

Radiotherapy

External beam radiotherapy delivered in fractions over a 6- to 8-week period is generally well tolerated, but approximately 10–15% of patients will develop bladder, bowel, or rectal complications. Local recurrence is common after radiotherapy alone (30–70%) and is therefore combined with systemic chemotherapy in an effort to reduce the need for radical cystectomy or to treat patients who are poor candidates for radical cystectomy.

Chemotherapy

Metastatic disease is present in 15% of patients with newly diagnosed bladder cancer, and metastases develop within 2 years in up to 40% of patients who were believed to have localized disease at the time of cystectomy or definitive radiotherapy. Cisplatin-based combination chemotherapy results in partial or complete responses in 15–45% of patients (see Table 39–4).

Combination chemotherapy has been integrated into trials of surgery and radiotherapy. It has been used to decrease recurrence rates with both modalities and to attempt bladder preservation in those treated with radiation. Chemotherapy should be considered before surgery in those with bulky lesions or those suspected of having regional disease, and recent evidence suggests that neoadjuvant chemotherapy may benefit all patients prior to planned cystectomy. Chemoradiation is best suited for those with T2 or limited T3 disease without ureteral obstruction. Alternatively, chemotherapy has been used after cystectomy in patients at high risk for recurrence.

Prognosis

The frequency of recurrence and progression are correlated with grade. Whereas progression may be noted in few grade I cancers (19–37%), it is common with poorly differentiated lesions (33–67%). Carcinoma in situ is most often found in association with papillary bladder cancers. Its presence identifies patients at increased risk for recurrence and progression.

At initial presentation, approximately 50–80% of bladder cancers are superficial: stage Ta, Tis, or T1. When properly treated, lymph node metastases and progression are uncommon in this population and survival is excellent at 81%. Five-year survival of patients with T2 and T3 disease ranges from 50% to 75% after radical cystectomy. Long-term survival for patients with metastatic disease at presentation is rare.

When to Refer

- All patients should be referred to an urologist. Hematuria often deserves evaluation with upper urinary tract imaging and cystoscopy.
- Histologic diagnosis and staging require endoscopic resection of tumor.

Cancers of the Ureter & Renal Pelvis

Cancers of the renal pelvis and ureter are rare and occur more commonly in patients with bladder cancer, smokers, those with Balkan nephropathy, those exposed to Thorotrast (a contrast agent with radioactive thorium in use until the 1960s), or those with a long history of analgesic abuse. The majority are urothelial cell carcinomas. Gross or microscopic hematuria is present in most patients, and flank pain secondary to bleeding and obstruction occurs less commonly. Like primary bladder tumors, urinary cytology is often positive. The most common signs identified at the time of IVU or CT include an intraluminal filling defect, unilateral nonvisualization of the collecting system, and hydronephrosis. Ureteral and renal pelvic tumors must be differentiated from calculi, blood clots, papillary necrosis, or inflammatory and infectious lesions. On occasion, upper urinary tract lesions are accessible for biopsy, fulguration, or resection using a ureteroscope. Treatment is based on the site, size, grade, depth of penetration, and number of tumors present. Most are excised with laparoscopic or open nephroureterectomy (renal pelvic and upper ureteral lesions) or segmental excision of the ureter (distal ureteral lesions). Endoscopic resection may be indicated in patients with limited renal function or focal, low-grade, cancers.

Renal Cell Carcinoma

Essentials of Diagnosis

- Gross or microscopic hematuria.
- Flank pain or mass in some patients.
- Systemic symptoms such as fever, weight loss may be prominent.

- Solid renal mass on imaging.

General Considerations

Renal cell carcinoma accounts for 2.6% of all adult cancers. In the United States, approximately 52,190 cases of renal cell carcinoma are diagnosed and 12,890 deaths result annually. Renal cell carcinoma has a peak incidence in the sixth decade of life and a male-to-female ratio of 2:1. It may be associated with a number of paraneoplastic syndromes (see below and Table 39–2).

The cause is unknown. Cigarette smoking is the only significant environmental risk factor that has been identified. Familial settings for renal cell carcinoma have been identified (von Hippel–Lindau syndrome) as well as an association with dialysis-related acquired cystic disease and specific genetic aberrations (eg, Xp11.2 translocation), but sporadic tumors are far more common.

Renal cell carcinoma originates from the proximal tubule cells. Various histologic cell types are recognized (clear cell, papillary, chromophobe, collecting duct and sarcomatoid).The TNM classification of the American Joint Cancer Committee for kidney cancer is shown in eTable 39–9.2.

eTable 39–9.2. TNM staging system for kidney cancer

T: Primary tumor	
Tx	Cannot be assessed
T0	No evidence of primary tumor
T1	Tumor 7 cm or less limited to kidney
T1a	Tumor 4 cm or less limited to kidney
T1b	Tumor more than 4 cm but not more than 7 cm limited to kidney
T2	Tumor > 7 cm limited to kidney
T3a	Tumor invades adrenal gland or perinephric tissue
T3b	Tumor extends into renal vein or vena cava
T3c	Tumor extends into renal vein or vena cava above diaphragm
T4	Tumor invades outside of Gerota fascia
N: Regional lymph nodes	
Nx	Cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node
N2	Metastasis in multiple nodes
M: Distant metastasis	
Mx	Cannot be assessed
M0	No distant metastasis
M1	Distant metastasis present

AJCC Cancer Staging Manual, 6th ed. Springer, 2002.

Clinical Findings

Symptoms and Signs

Historically, 60% of patients presented with gross or microscopic hematuria. Flank pain or an abdominal mass was detected in approximately 30% of cases. The triad of flank pain, hematuria, and mass was found in only 10–15% of patients and is often a sign of advanced disease. Fever may be present as a paraneoplastic symptom (see Table 39–2). Symptoms of metastatic disease (cough, bone pain) occur in 20–30% of patients at presentation. Because of the widespread use of ultrasound and CT scanning, renal tumors are frequently detected incidentally in individuals with no urologic symptoms. There has been profound stage migration toward lower stages of disease over the past 10 years, likely due to the increased use of abdominal imaging. However, population mortality rates remain stable.

Laboratory Findings

Hematuria is present in 60% of patients. Erythrocytosis from increased erythropoietin production occurs in 5%, though anemia is more common; hypercalcemia may be present in up to 10% of patients. Stauffer syndrome is a reversible syndrome of hepatic dysfunction in the absence of metastatic disease.

Imaging

Renal masses are often first identified by abdominal ultrasonography or CT. CT scanning is the most valuable imaging test for renal cell carcinoma. It confirms the character of the mass and further stages the lesion with respect to regional lymph nodes, renal vein, or hepatic involvement. CT also provides valuable information regarding the contralateral kidney (function, bilaterality of neoplasm). Chest radiographs exclude pulmonary metastases, and bone scans should be performed for large tumors and in patients with bone pain or elevated alkaline phosphatase levels. MRI and duplex Doppler ultrasonography are excellent methods of assessing for the presence and extent of tumor thrombus within the renal vein or vena cava.

Differential Diagnosis

Solid lesions of the kidney are renal cell carcinoma until proved otherwise. Other solid masses include angiomyolipomas (fat density usually visible by CT), urothelial cell cancers of the renal pelvis (more centrally located, involvement of the collecting system, positive urinary cytologic tests), adrenal tumors (superoanterior to the kidney) and oncocytomas (indistinguishable from renal cell carcinoma preoperatively), and renal abscesses.

Treatment

Radical nephrectomy is the primary treatment for localized renal cell carcinoma. Patients with a single kidney, bilateral lesions, or significant medical renal disease should be considered for partial nephrectomy. Patients with a normal contralateral kidney and good renal function but a small cancer are also candidates for partial nephrectomy. The use of radiofrequency or cryosurgical ablation is being studied.

No effective chemotherapy is available for metastatic renal cell carcinoma. Vinblastine is the single most effective agent, with short-term partial response rates of 15%. Bevacizumab can prolong time to progression in those with metastatic disease (see Table 39–4). Biologic response modifiers have received much attention, including interferon- and interleukin-2. Partial response rates of 15–20% and 15–35%, respectively, have been reported. Responders tend to have lower tumor burdens, metastatic disease confined to the lung, and a high performance status. Patients with metastatic kidney cancer and good performance status who have resectable primary tumors should undergo cytoreductive nephrectomy. Two randomized trials have shown a survival benefit of surgery followed by the use of systemic therapy—specifically, biologic response modifiers—compared with the use of systemic therapy alone.

Several targeted drugs, specifically VEGF and Raf-kinase inhibitors, are effective (40% response rates) in patients with advanced kidney cancer. The drugs are oral agents, well tolerated, and particularly active for clear cell carcinoma. The appropriate timing and combination of these agents, with and without surgery and cytokine therapy, remains to be determined.

Prognosis

After radical nephrectomy, tumors confined to the renal capsule (T1–T2) demonstrate 5-year disease-free survivals of 90–100%. Tumors extending beyond the renal capsule (T3 or T4) and node-positive tumors have 50–60% and 0–15% 5-year disease-free survival, respectively. One subgroup of patients with nonlocalized disease has reasonable long-term survival, namely, those with solitary resectable metastases. In this setting, radical nephrectomy with resection of the metastasis results in 5-year disease-free survival rates of 15–30%.

When to Refer

- Patients with solid renal masses require further evaluation and should be referred to an urologist.

- Surgical excision of renal cell carcinoma remains the gold standard.
- Patients with metastatic disease should be referred to an oncologist.

Other Primary Tumors of the Kidney

Oncocytomas account for 3–5% of renal tumors, are usually benign, and are indistinguishable from renal cell carcinoma on preoperative imaging. These tumors are seen in other organs, including the adrenals, salivary glands, and thyroid and parathyroid glands.

Angiomyolipomas are rare benign tumors composed of fat, smooth muscle, and blood vessels. They are most commonly seen in patients with tuberous sclerosis (often multiple and bilateral) or in young to middle-aged women. CT scanning may identify the fat component, which is diagnostic for angiomyolipoma. Asymptomatic lesions less than 5 cm in diameter usually do not require intervention; large lesions can spontaneously bleed. Acute bleeding can be treated by angiographic embolization or, in rare cases, nephrectomy. Lesions over 5 cm are often prophylactically treated with angioembolization to reduce the risk of bleeding.

Secondary Tumors of the Kidney

The kidney is not an infrequent site for metastatic disease. Of the solid tumors, lung cancer is the most common (20%), followed by breast (10%), stomach (10%), and the contralateral kidney (10%). Lymphoma, both Hodgkin and non-Hodgkin, may also involve the kidney, although it tends to be appear as a diffusely infiltrative process resulting in renal enlargement rather than a discrete mass.

Primary Tumors of the Testis

Essentials of Diagnosis

- Commonest neoplasm in men aged 20–35 years.
- Typical presentation as a patient-identified painless nodule.
- Orchiectomy necessary for diagnosis.

General Considerations

Malignant tumors of the testis are rare, with approximately two to three new cases per 100,000 males reported in the United States each year. Ninety to 95 percent of all primary testicular tumors are germ cell tumors and can be divided into two major categories: **nonseminomas**, including embryonal cell carcinoma (20%), teratoma (5%), choriocarcinoma (< 1%), and mixed cell types (40%); and **seminomas** (35%). The remainder of primary testicular tumors are nongerminal neoplasms (Leydig cell, Sertoli cell, gonadoblastoma). The lifetime probability of developing testicular cancer is 0.2% for an American white male. For the purposes of this review, only germ cell tumors will be considered.

Approximately 5% of testicular tumors develop in a patient with a history of cryptorchism, with seminoma being the most common. However, 5–10% of these tumors occur in the contralateral, normally descended testis. The relative risk of development of malignancy is highest for the intra-abdominal testis (1:20) and lower for the inguinal testis (1:80). Placement of the cryptorchid testis into the scrotum (orchidopexy) does not alter the malignant potential of the cryptorchid testis but does facilitate routine examination and tumor detection.

Testicular cancer is slightly more common on the right than the left, paralleling the increased incidence of cryptorchidism on the right side. One to 2 percent of primary testicular tumors are bilateral and up to 50% of these men have a history of unilateral or bilateral cryptorchidism. Primary bilateral testicular tumors may occur synchronously or asynchronously but tend to be of the same histology. Seminoma is the most common histologic finding in bilateral *primary* testicular tumors, while malignant lymphoma is the most common bilateral testicular tumor overall.

In animal models, exogenous estrogen administration during pregnancy has been associated with an increased development of testicular tumors with relative risk ranging from 2.8 to 5.3. Other acquired factors such as trauma and infection-related testicular atrophy have been associated with testicular tumors; however, a causal relationship has not been established.

Clinical Findings

Symptoms and Signs

The most common symptom of testicular cancer is painless enlargement of the testis. Sensations of heaviness are not unusual. Patients are usually the first to recognize an abnormality, yet the typical delay in seeking medical attention ranges from 3 to 6 months. Acute testicular pain resulting from intratesticular hemorrhage occurs in approximately 10% of cases. Ten percent of patients are asymptomatic at presentation, and 10% manifest symptoms relating to metastatic disease such as back pain (retroperitoneal metastases), cough (pulmonary metastases), or lower extremity edema (vena cava obstruction).

A discrete mass or diffuse testicular enlargement is noted in most cases. Secondary hydroceles may be present in 5–10% of cases. In advanced disease, supraclavicular adenopathy may be present, and abdominal examination may reveal a mass. Gynecomastia is seen in 5% of germ cell tumors.

Laboratory Findings

Several serum markers are important in the diagnosis and monitoring of testicular carcinoma, including human chorionic gonadotropin (hCG), -fetoprotein, and LD. -Fetoprotein is never elevated with pure seminomas, and while hCG is occasionally elevated in seminomas, levels tend to be lower than those seen with nonseminomas. LD may be elevated with either type of tumor. Liver function tests may be elevated in the presence of hepatic metastases, and anemia may be present in advanced disease.

Imaging

Scrotal ultrasound can readily determine whether a mass is intratesticular or extratesticular. Once the diagnosis of testicular cancer has been established by inguinal orchiectomy, clinical staging of the disease is accomplished by chest, abdominal, and pelvic CT scanning.

Staging

In a commonly used staging system for nonseminoma germ cell tumors, a stage A lesion is confined to the testis; stage B demonstrates regional lymph node involvement in the retroperitoneum; and stage C indicates distant metastasis. For seminoma, the M.D. Anderson system is commonly used. In this system, a stage I lesion is confined to the testis, a stage II lesion has spread to the retroperitoneal lymph nodes, and a stage III lesion has supradiaphragmatic nodal or visceral involvement.The TNM classification of the American Joint Cancer Committee for testis cancer is shown in eTable 39–9.3.

eTable 39–9.3. TNM staging system for testicular cancer	
T: Primary tumor	
Tx	Cannot be assessed
T0	No evidence of primary tumor
Tis	Intratubular cancer (carcinoma in situ)
T1	Limited to testis without vascular invasion
T2	Invades beyond tunica albuginea or into epididymis, or limited to testis with vascular invasion
T3	Invades spermatic cord
T4	Invades scrotum
N: Regional lymph nodes	
Nx	Cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node 2 cm or less
N2	Metastasis in a single lymph node > 2 cm and < 5 cm or multiple nodes none > 5 cm
N3	Metastasis in lymph node > 5 cm
M: Distant metastasis	
Mx	Cannot be assessed
M0	No distant metastasis
M1a	Metastasis to nonregional lymph node(s) or lung(s)

Reproduced, with permission, from Greene FL et al (editors).

AJCC Cancer Staging Manual, 6th ed. Springer, 2002**.**

Differential Diagnosis

An incorrect diagnosis is made at the initial examination in up to 25% of patients with testicular tumors. Scrotal ultrasonography should be performed if any uncertainty exists with respect to the diagnosis. Although most intratesticular masses are malignant, a benign lesion—epidermoid cyst—may rarely be seen. Epidermoid cysts are usually very small benign nodules located just underneath the tunica albuginea; occasionally, however, they can be large.

Treatment

Inguinal exploration with early vascular control of the spermatic cord structures is the initial intervention. If cancer cannot be excluded by examination of the testis, radical orchiectomy is warranted. Scrotal approaches and open testicular biopsies should be avoided. Further therapy depends on the histology of the tumor as well as the clinical stage.

Stage I and IIa **seminomas** (retroperitoneal disease < 10 cm in diameter) are treated by radical orchiectomy and retroperitoneal irradiation. Patients with clinical stage I disease may be candidates for surveillance or single-agent carboplatin. Seminomas of stage IIb (> 10 cm retroperitoneal involvement) and stage III receive primary chemotherapy (etoposide and cisplatin or cisplatin, etoposide, and bleomycin). Surgical resection of residual retroperitoneal masses is warranted if the mass is larger than 3 cm in diameter, under which circumstances 40% will harbor residual carcinoma.

Up to 75% of clinical stage I **nonseminomas** are cured by orchiectomy alone. Selected patients who meet specific criteria may be offered surveillance after orchiectomy. These criteria are as follows: (1) tumor is confined within the tunica albuginea; (2) tumor does not demonstrate vascular invasion; (3) tumor markers normalize after orchiectomy; (4) radiographic imaging of the chest and abdomen shows no evidence of disease; and (5) the patient is reliable. Patients most likely to experience relapse on a surveillance regimen include those with predominantly embryonal cancer and those with vascular or lymphatic invasion identified in the orchiectomy specimen. Surveillance needs to be considered an active process both by the clinician and by the patient. Patients are followed monthly for the first 2 years and bimonthly in the third year. Tumor markers are obtained at each visit, and chest radiographs and CT scans are obtained every 3 months. Follow-up continues beyond the initial 3 years; however, the 80% of relapses will occur within the first 2 years. With rare exceptions, patients who relapse can be cured by chemotherapy or surgery. Alternatives to surveillance include adjuvant chemotherapy (bleomycin, etoposide, cisplatin) and retroperitoneal lymph nodes dissection.

Patients with bulky retroperitoneal disease (> 3 cm nodes) or metastatic nonseminomas are treated with primary cisplatin-based combination chemotherapy following orchiectomy (etoposide and cisplatin or cisplatin, etoposide, and bleomycin) (see Table 39–4). If tumor markers normalize and a residual mass greater than 1 cm persists on imaging studies, the mass is resected because 20% of the time it will harbor viable cancer and 40% of the time it will harbor teratoma. Even if patients have a complete response to chemotherapy, some clinicians advocate retroperitoneal lymphadenectomy since 10% of patients may harbor residual carcinoma and 10% may have teratoma in the retroperitoneum. If tumor markers fail to normalize following primary chemotherapy, salvage chemotherapy is required (cisplatin, etoposide, ifosfamide).

Prognosis

The 5-year disease-free survival rates for stage I and IIa **seminomas** (retroperitoneal disease < 10 cm in diameter) treated by radical orchiectomy and retroperitoneal irradiation are 98% and 92–94%, respectively. Ninety-five percent of patients with stage III disease attain a complete response following orchiectomy and chemotherapy. Patients with bulky retroperitoneal or disseminated disease treated with primary chemotherapy followed by surgery have a 5-year disease-free survival rate of 55–80%. The 5-year disease-free survival rate for patients with stage A **nonseminomas** (includes all treatments, orchiectomy and subsequently) ranges from 96% to 100%. For low-volume stage B disease, 90% 5-year disease-free survival is expected.

When to Refer

Patients with solid masses of the testis should be referred to a urologist.

Albers P et al. Randomized phase III trial comparing retroperitoneal lymph node dissection with one course of bleomycin and etoposide plus cisplatin chemotherapy in the adjuvant treatment of clinical stage I noneminomatous testicular germ cell tumors: AUO trial AH 01/94 by the German Testicular Cancer Study Group. Secondary Tumors of the Testis

Secondary tumors of the testis are rare. In men over the age of 50 years, lymphoma is the most common testis tumor, and overall it is the most common secondary neoplasm of the testis, accounting for 5% of all testicular tumors. It may be seen in three clinical settings: (1) late manifestation of widespread lymphoma, (2) the initial presentation of clinically occult disease, and (3) primary extranodal disease. Radical orchiectomy is indicated to make the diagnosis. Prognosis is related to the stage of disease.

Metastasis to the testis is rare. The most common primary site of origin is the prostate, followed by the lung, gastrointestinal tract, melanoma, and kidney.

Cancer Complications & Emergencies

Cancer is a chronic disease, but acute emergency complications (eg, spinal cord compression, superior vena cava syndrome, malignant effusions) or generalized systemic effects (eg, hypercalcemia, opportunistic infections, disseminated intravascular coagulation, hyperuricemia) may occur as a consequence of local invasion of the cancer. Superior vena cava syndrome is discussed in Chapter 12: Blood Vessel & Lymphatic Disorders and disseminated intravascular coagulation is discussed in Chapter 13: Blood Disorders.

Spinal Cord Compression

Essentials of Diagnosis

- Occurs as a complication of metastatic solid tumor lymphoma or multiple myeloma.
- Back pain is presenting symptom in most patients.
- Prompt diagnosis is essential because once a severe neurologic deficit develops, it is generally irreversible.
- Emergent treatment may prevent or potentially reverse paresis and urinary and bowel incontinence.

General Considerations

Cancers that cause spinal cord compression most commonly metastasize to the vertebral bodies, resulting in physical damage to the spinal cord from edema, hemorrhage, and ischemia. Persistent compression can result in irreversible changes to the myelin sheaths resulting in permanent neurologic impairment.

Prompt diagnosis and therapeutic intervention are essential, since the probability of reversing neurologic symptoms largely depends on the duration of symptoms. Patients who are treated promptly after symptoms appear may have partial or complete return of function and, depending on tumor sensitivity to specific treatment, may respond favorably to subsequent anticancer therapy.

Clinical Findings

Symptoms and Signs

Back pain at the level of the tumor mass occurs in over 80% of cases and may be aggravated by lying down, weight bearing, sneezing, or coughing; it usually precedes the development of neurologic symptoms or signs. Since involvement is usually epidural, a mixture of nerve root and spinal cord symptoms often develops. Progressive weakness and sensory changes commonly occur. Bowel and bladder symptoms progressing to incontinence are late findings.

The initial findings of impending cord compression may be quite subtle, and there should be a high index of suspicion when back pain or weakness of the lower extremities develops in cancer patients.

Imaging

MRI is usually the initial imaging procedure of choice in a cancer patient with new-onset back pain. When there are neurologic findings suggesting spinal cord compression, an emergent MRI should be obtained. It is important to obtain a survey of the entire spine to define all areas of tumor involvement for treatment planning purposes.

Bone radiographs, if done, may show evidence of vertebral body or pedicle destruction by the cancer. However, bone radiographs are neither sensitive nor specific and therefore are not helpful in diagnosis or treatment planning. If the back pain symptoms are nonspecific, bone scan imaging may be useful as a screening procedure.

Treatment

Patients found to have epidural impingement of the spinal cord should be given corticosteroids immediately. The initial dose is 10–100 mg intravenously followed by 4–6 mg every 6 hours intravenously or orally. Patients without a known diagnosis of cancer should have emergent surgery to relieve the impingement and obtain a pathologic specimen. Patients with a single area of compression due to solid tumors are best treated with surgical decompression followed by radiation therapy. A randomized trial comparing surgery followed by radiation therapy with radiation therapy alone showed better outcomes (ie, improved ability to ambulate and improved bladder and bowel functions) in persons who had surgery followed by radiation therapy. If multiple vertebral body levels are involved with cancer, radiation therapy is the preferred treatment option. Corticosteroids are generally tapered toward the end of radiation therapy.

Malignant Effusions

Essentials of Diagnosis

- Occur in pleural, pericardial, and peritoneal spaces.
- Caused by direct neoplastic involvement of serous surface or obstruction of lymphatic drainage.
- Half of undiagnosed effusions in patients not known

to have cancer are malignant.

General Considerations

The development of an effusion in the pleural, pericardial, or peritoneal space may be the initial finding in a patient with cancer, or an effusion may appear during the course of disease progression. Direct involvement of the serous surface with tumor is the most frequent initiating cause of the accumulation of fluid. The most common malignancies causing pleural and pericardial effusions are lung and breast cancers; the most common malignancies associated with malignant ascites are ovarian, colorectal, stomach, and pancreatic cancers.

Clinical Findings

Symptoms and Signs

Patients with pleural and pericardial effusions complain of shortness of breath and orthopnea. Patients with ascites complain of abdominal distention and discomfort. Cardiac tamponade causing pressure equalization in the chambers impairing both filling and cardiac output can be a life-threatening event. Signs of tamponade include tachycardia, pulsus paradoxus, and hypotension. Signs of pleural effusions include decreased breath sounds, egophony, and percussion dullness.

Laboratory Findings

Malignancy is confirmed as the cause of an effusion when analysis of the fluid specimen shows malignant cells in either the cytology or cell block specimen.

Imaging

The presence of effusions can be confirmed with radiographic studies or ultrasonography.

Differential Diagnosis

The differential diagnosis of a malignant pleural or pericardial effusion includes benign processes, such as congestive heart failure, pulmonary embolism, trauma, and infection.

The differential diagnosis of malignant ascites includes similar benign processes, such as congestive heart failure and infections; cirrhosis and pancreatic disease also cause ascites.

Bloody effusions are usually due to cancer, but a bloody pleural effusion can also be due to pulmonary embolism or trauma. Chylous pleural or ascitic fluid is generally associated with obstruction of lymphatic drainage as might occur in lymphomas.

Treatment

In some cases, treatment of the underlying cancer with chemotherapy can cause regression of the effusions; however, not uncommonly, the presence of an effusion is an end-stage manifestation of the disease. In this situation, decisions regarding management are in large part dictated by the patient's symptoms and goals of care.

Pleural Effusion

A pleural effusion that is symptomatic may be managed initially with a **large volume thoracentesis**. With some patients, the effusion slowly reaccumulates, which allows for periodic thoracentesis when the patient becomes symptomatic. However, in most patients, the effusion reaccumulates quickly, causing rapid return of symptoms of shortness of breath. For those patients, several options exist for management. **Chest tube drainage followed by pleurodesis** is the preferred option for patients with a reasonable life expectancy. Patients are generally hospitalized for 3–7 days. The procedure involves placement of a chest tube that is connected to closed water seal drainage. Fluid is allowed to drain over several days. After lung expansion is confirmed on a chest radiograph, a sclerosing agent (such as talc slurry) is injected into the catheter. Other agents that can be used include doxycycline or bleomycin. Patients should be premedicated with analgesics and placed in a variety of positions in order to distribute the drug through the pleural spaces. Pleurodesis will not be successful if the lung cannot be reexpanded; these patients may be treated with the placement of a shunt or continued use of catheter drainage. Until recently, standard management had been to hold sclerosis until the chest tube drainage had decreased to less than 100 mL/d; a recent randomized trial comparing immediate pleurodesis after initial drainage with waiting until drainage had decreased to 100 mL/d showed no difference in pleurodesis efficacy between the two groups.

Pericardial Effusion

Fluid may be removed by a needle aspiration or by placement of a catheter for more thorough drainage. As with pleural effusions, most pericardial effusions will reaccumulate. Management options for recurrent, symptomatic effusions include catheter drainage followed by sclerosis with such agents as doxycycline or bleomycin or by pericardiectomy.

Malignant Ascites

Patients with malignant ascites not responsive to chemotherapy are generally treated with repeated large volume paracenteses. As the frequency of drainage to maintain comfort can compromise the patient's quality of life, other alternatives include placement of a catheter or port so that the patient, family member, or visiting nurse can drain fluid as needed at home. Another option is placement of a peritoneovenous shunt; this can be considered for a select group of patients with life expectancy greater than 3 months and fluid that is nonviscous, nonbloody, and nonloculated.

Hypercalcemia

Essentials of Diagnosis

- Usually symptomatic and severe (15 mg/dL).
- Most common paraneoplastic endocrine syndrome, accounting for most cases of hypercalcemia among

inpatients.

- The neoplasm is clinically apparent in nearly all cases when hypercalcemia is detected.

General Considerations

Hypercalcemia affects 20–30% of cancer patients at some point during their illness. The most common cancers causing hypercalcemia are myeloma, breast carcinoma, and non–small cell lung cancer. The presence of bone metastasis is not an essential feature of the syndrome, since hypercalcemia can be caused by systemic effects of tumor-released proteins (see The Paraneoplastic Syndromes above).

Clinical Findings

Symptoms and Signs

Symptoms and signs of hypercalcemia can be subtle; the severity of symptoms not only depends on the degree of hypercalcemia but also the rate at which the calcium level rises. Early symptoms typically include anorexia, nausea, fatigue, constipation, and polyuria; later findings may include muscular weakness and hyporeflexia, confusion, psychosis, tremor, and lethargy.

Laboratory Findings

Symptoms and signs are caused by free calcium; as calcium is bound by protein in the serum, the measured serum calcium will underestimate the free or ionized calcium in patients with low albumin levels. In the setting of hypoalbuminemia, the corrected serum calcium should be calculated by one of several available formulas (eg, corrected calcium = measured calcium – measured albumin + 4). Alternatively, the free calcium can be measured. When the corrected serum calcium rises above 12 mg/dL, sudden death due to cardiac arrhythmia or asystole may occur. The presence of hypercalcemia does not invariably indicate a dismal prognosis, especially in patients with breast cancer, myeloma, or lymphoma.

In the absence of signs or symptoms of hypercalcemia, a laboratory finding of elevated serum calcium should be retested immediately to exclude the possibility of error.

ECG

Electrocardiography often shows a shortening of the QT interval (see ECG).

Fig.

Hypercalcemia in a patient with carcinoma. The QT interval is only 0.28–0.3 because of virtual absence of the QT segment. (Reproduced, with permission, from

Goldschlager N, Goldman MJ: *Principles of Clinical Electrocardiography*, 13th ed. Originally published by Appleton & Lange. Copyright © 1989 by The McGraw-Hill Companies, Inc.)

Treatment

Emergency management should begin with the initiation of intravenous fluids with 0.9% saline at 100–200 mL/h to ensure rehydration with brisk urinary output of the often volume-depleted patient. If kidney function is normal or only marginally impaired, a bisphosphonate should be given. Choices include pamidronate, 60–90 mg intravenously over 2–4 hours, or zoledronic acid, 4 mg intravenously over several minutes. Zoledronic acid is more potent than pamidronate and has the advantage of a shorter administration time as well as a longer duration of effect but is more associated with the uncommon but serious side effect of osteonecrosis of the jaw. Once hypercalcemia is controlled, treatment directed at the cancer should be initiated if possible. Commonly, though, hypercalcemia occurs in patients with cancers that are unresponsive to treatment. In the event that the hypercalcemia becomes refractory to repeated doses of bisphosphonates, other agents that can help control hypercalcemia (at least temporarily) include gallium nitrate, calcitonin, and mithramycin; corticosteroids can be useful in patients with myeloma and lymphoma.

Salmon calcitonin, 4–8 international units/kg given subcutaneously or intramuscularly every 12 hours, can be useful in patients with kidney disease; its onset of action is within hours but its hypocalcemic effect will wane in 2–3 days.

Hyperuricemia & Tumor Lysis Syndrome

Essentials of Diagnosis

- Complication of treatment-associated tumor lysis of hematologic malignancies as well as rapidly proliferating malignancies.
- May be worsened by thiazide diuretic use.
- Rapid increase in serum uric acid can result in acute urate nephropathy caused by uric acid crystallization.
- Reducing pre-chemotherapy serum uric acid is fundamental to preventing urate nephropathy.

General Considerations

Tumor lysis syndrome (TLS) is seen most commonly following treatment of hematologic malignancies, such as acute lymphoblastic leukemia and Burkitt lymphoma. However, TLS can develop from any tumor highly sensitive to chemotherapy. TLS is caused by the massive release of cellular material including nucleic acids, proteins, phosphorus, and potassium. If both the metabolism and excretion of these breakdown products are overwhelmed, hyperuremia, hyperphosphatemia, and hyperkalemia will develop abruptly. Acute kidney injury may develop from the hyperuremia, further exacerbating the hyperphosphatemia and hyperkalemia.

Clinical Findings

Symptoms of hyperphosphatemia include nausea and vomiting as well as seizures. Also, with high levels of phosphorus, co-precipitation with calcium can cause renal tubule blockage further exacerbating the kidney injury. Hyperkalemia, due to release of intracellular potassium and with excretion impaired by the kidney disease, can cause arrhythmias and sudden death.

Treatment

Prevention is the most important factor in the management of TLS. Guidelines for management of TLS have been developed by the American Society of Clinical Oncology and include aggressive hydration prior to initiation of chemotherapy as well as during and after completion of the chemotherapy. Administration of fluid helps keep urine flowing and facilitate excretion of uric acid and phosphorus. For the patients with moderate risk of developing TLS, allopurinol (which blocks the enzyme xanthine oxidase and therefore the formation of uric acid from purine breakdown) should be given before starting chemotherapy at an oral dose of 100 mg/m^2 every 8 hours (maximum 800 mg/d) with dose adjustments for kidney disease. For patients at high risk for developing TLS or in whom hyperuricemia develops despite treatment with allopurinol, rasburicase 0.1–0.2 mg/kg/d is given intravenously for 1–7 days. Rasburicase is a recombinant urate oxidase that converts uric acid into the more soluble form resulting in rapid decline in uric acid levels. Rasburicase cannot be given to patients with known glucose 6-phosphate dehydrogenase (G6PD) deficiency nor can it be given to pregnant or lactating women. One of the mainstays of TLS management, systemic bicarbonate infusions to alkalinize the urine, is no longer recommended. Laboratory values should be monitored following initiation of chemotherapy; elevated potassium or phosphorus levels need to be promptly managed.

When to Refer

Should urinary output drop or creatinine level rise, a nephrologist should be consulted to evaluate the need for dialysis.

Coiffier B et al. Guidelines for the management of pediatric and adult tumor lysis syndrome: an evidence-based review. J Clin Oncol. 2008 Jun 1;26(16):2767–78. [PMID: 18509186]

Higdon ML et al. Treatment of oncologic emergencies. Am Fam Physician. 2006 Dec 1;74(11):1873–80. [PMID: 17168344]

Infections

Chapter 30: Common Problems in Infectious Diseases & Antimicrobial Therapy provides a more detailed discussion of infections in the immunocompromised patient.

Essentials of Diagnosis

- In patients with neutropenia, infection is a medical emergency.
- The presence of fever, although sometimes attributable to other causes, must be assumed to be due to an infection.

General Considerations

Many patients with disseminated neoplasms have increased susceptibility to infection. In some patients, this results from impaired defense mechanisms (eg, acute leukemia, Hodgkin disease, multiple myeloma, chronic lymphocytic leukemia); in others, it results from the myelosuppressive and immunosuppressive effects of cancer chemotherapy or a combination of these factors. Complicating impaired defense mechanisms are the frequent presence of indwelling catheters, impaired mucosal surfaces, and colonization with more virulent hospital-acquired pathogens.

The source of a neutropenic febrile episode is determined in about 30% of cases through blood, urine, or sputum cultures. The bacterial organisms accounting for the majority of infections in cancer patients include gram-negative bacteria (*Escherichia coli, Klebsiella, Pseudomonas, Enterobacter*) and gram-positive bacteria (coagulase-negative *Staphylococcus, Staphylococcus aureus, Streptococcus pneumoniae, Corynebacterium,* and streptococci). There has been a trend over the last decade of an increasing percentage of gram-positive organisms. The risk of bacterial infections rises when the granulocyte count is below 1000/mcL; the risk dramatically increases when the count falls below 100/mcL.

Clinical Findings

Appropriate cultures (eg, blood, sputum, urine, cerebrospinal fluid) should always be obtained before starting therapy. Two sets of blood cultures should be drawn; if the patient has an indwelling catheter, one of the cultures should be drawn from the line. A chest radiograph should also be obtained.

Treatment

Empiric antibiotic therapy needs to be initiated immediately in the febrile, neutropenic patient. The choice of antibiotics depends on a number of different factors including the patient's clinical status and any localizing source of infection. If the patient is clinically well, monotherapy with an intravenous -lactam with anti-*Pseudomonas* activity (cefepime, ceftazidime, imipenem/cilastatin, piperacillin/tazabactam) should be started. If the patient is clinically ill with hypotension or hypoxia, an aminoglycoside or fluoroquinolone should be added for "double" gram-negative bacteria coverage. If there is a strong suspicion of a gram-positive organism, such as from *S aureus* catheter infection, vancomycin can be given empirically. In some instances, patients may be treated with oral antibiotics and potentially in the outpatient setting. The Infectious Disease Society of America (IDSA) has published recommendations for antibiotic use in these low-risk patients. These patients must have an expected neutropenic timeframe of 7 days or less and not have comorbidities or signs of hemodynamic instability, gastrointestinal symptoms, altered mental status, pulmonary issues (an infiltrate, hypoxia, or underlying chronic obstructive pulmonary disease) and their liver and kidney function must not be impaired. If a patient is to be treated as an outpatient, he or she must also have good support at home and easy access to returning to the hospital if the clinical status worsens.

Antibiotics should be continued until the neutrophil count is rising and greater than 500/mcL for at least 1 day and the patient has been afebrile for 2 days. If an organism is identified through the cultures, the antibiotics should be adjusted to the antibiotic sensitivities of the isolate; treatment should be continued for the appropriate period of time and at least until the neutrophil count recovers.

For the neutropenic patient who is persistently febrile despite broad-spectrum antibiotics, an empiric antifungal drug should be added (amphotericin B, caspofungin, itraconazole, voriconazole, or liposomal amphotericin B).

Segal BH et al. Prevention and treatment of cancer-related infections. J Natl Compr Canc Netw. 2008 Feb;6(2):122–74. [PMID: 18319048]

Systemic Cancer Therapy

Detailed guidelines from the NCCN for cancer treatment can be found at www.nccn.org.

Use of cytotoxic drugs, hormones, antihormones, and biologic agents has become a highly specialized and increasingly effective means of treating cancer, with therapy usually administered by a medical oncologist. Selection of specific drugs or protocols for various types of cancer has traditionally been based on results of prior clinical trials; however, many patients have drug-resistant tumors. Molecular mechanisms of drug resistance continue to be the subject of intense study. Described mechanisms of drug resistance include impaired membrane transport of drugs, enhanced drug metabolism, mutated target proteins, and blockage of apoptosis due to mutations in cell cycle proteins. Cancer cells may initially be resistant to chemotherapy or acquire resistance when exposed to drugs.

Toxicity & Dose Modification of Chemotherapeutic Agents

Use of chemotherapy to treat cancer is generally guided by results from clinical trials in individual tumor types. The complexity of treating cancer has increased over the last decade as more drugs, including those with novel mechanisms of action, have been approved by the Food and Drug Administration and introduced into general practice. Drug side effects and toxicities must be anticipated and carefully monitored. The short- and long-term toxicities of individual drugs are listed in Tables 39–10 and 39–11. Decisions on dose modifications for toxicities should be guided by the intent of therapy. In the palliative setting where the aim of therapy is to improve symptoms and quality of life, lowering doses to minimize toxicity is commonly done. However, when the goal of treatment is cure, dosing frequency and intensity should be maintained whenever possible. Cancer chemotherapy should be given and monitored by a medical oncologist or hematologist.

Table 39–10. Chemotherapeutic agents: Dosage and toxicity.

Chemotherapeutic Agent	Usual Adult Dosage	Acute Toxicity	Delayed Toxicity
Alkylating Agents—Nitrogen Mustards			
Bendamustine	100–120 mg/m^2 intravenously	Hypersensitivity	Myelosuppression,

(Treanda)	every 3–4 weeks	reaction, nausea, vomiting, skin reaction	pyrexia, fatigue
Cyclophosphamide (Cytoxan)	500–1000 mg/m^2 intravenously every 3 weeks; 100 mg/m^2/d orally for 14 days every 4 weeks	Nausea and vomiting	Myelosuppression, hemorrhagic cystitis, alopecia, cardiotoxicity with high-dose therapy, SIADH
Estramustine (Emcyt)	14 mg/kg/d orally in three or four divided doses	Nausea, vomiting, diarrhea	Gynecomastia, thromboembolism, edema
Ifosfamide (Ifex)	1200 mg/m^2 daily for 5 days intravenously every 3 weeks	Nausea and vomiting	Myelosuppression, hemorrhagic cystitis, neurotoxicity, alopecia, SIADH
Mechlorethamine	0.4 mg/kg intravenously	Severe nausea and	Myelosuppression,

(nitrogen mustard, Mustargen)	every 3–6 weeks; or 6 mg/m^2 intravenously on days 1 and 8 every 4 weeks	vomiting, severe vesicant	increased risk of secondary malignancies
Melphalan (Alkeran)	0.25 mg/kg/d or 8–10 mg/m^2/d orally for 4 days every 4–6 weeks; 16 mg/m^2 intravenously every 2–4 weeks; 200 mg/m^2 intravenously for bone marrow transplant	Nausea, vomiting, diarrhea, hypersensitivity (IV), mucositis (IV)	Myelosuppression, increased risk of secondary malignancies
Alkylating Agents—Platinum Analogs			
Carboplatin (Paraplatin)	Area under the curve (AUC)-based dosing use Calvert equation [Dose (mg) = AUC x (GFR + 25)]AUC = 2–7 mg/mL/min every	Nausea, vomiting, hypersensitivity reaction	Myelosuppression, electrolyte disturbances, peripheral neuropathy, nephrotoxicity (less

	2–4 weeks; or 200–400 mg/m^2 intravenously every 4 weeks		common than with cisplatin)
Cisplatin (Platinol)	50–100 mg/m^2 intravenously every 3–4 weeks; 20 mg/m^2/d intravenously for 5 days every 3 weeks	Severe nausea and vomiting	Nephrotoxicity, ototoxicity, peripheral neuropathy, myelosuppression, electrolyte disturbances
Oxaliplatin (Eloxatin)	85–130 mg/m^2 intravenously every 2–3 weeks	Peripheral neuropathy triggered or exacerbated by cold, nausea, vomiting, diarrhea, rare anaphylactic reactions	Peripheral neuropathy, myelosuppression

Alkylating Agents—Triazenes			
Dacarbazine (DTIC-Dome)	375 mg/m^2 intravenously on day 1 and 15 every 4 weeks, 250 mg/m^2 intravenously for 5 days	Severe nausea and vomiting, anorexia	Myelosuppression, photosensitivity, hepatotoxicity, flu-like syndrome
Procarbazine (Matulane)	60–100 mg/m^2 orally for 14 days every 4 weeks	Nausea and vomiting	Myelosuppression; disulfiram-like reaction with alcohol; caution with tyramine-containing foods, tricyclic antidepressants, and sympathomimetic agents – MAO inhibition; increased risk of

			secondary malignancies
Temozolomide (Temodar)	75 mg/m^2 orally daily during radiation for 42 days 150–200 mg/m^2 orally for 5 days every 4 weeks	Nausea, vomiting, headache, constipation	Myelosuppression
Alkylating Agents—Miscellaneous			
Busulfan (Myleran)	1–8 mg daily orally	Nausea and vomiting	Myelosuppression, mucositis, hyperpigmentation of skin, rare pulmonary fibrosis, hepatic veno-occlusive disease with high doses (> 16 mg/d in transplant patients)
Chlorambu	0.1–0.2 mg/kg/d	None	Myelosuppre

cil (Leukeran)	orally for 3–6 weeks; or 0.4 mg/kg pulse every 4 weeks		ssion, rare pulmonary toxicity, skin reaction, increased risk of secondary malignancies with prolonged use
Lomustine (CCNU)	100–130 mg/m^2 orally every 6 weeks	Nausea and vomiting	Myelosuppression, pulmonary toxicity
Antimetabolites—Folate Antagonists			
Methotrexate (MTX; Trexall)	Intrathecal: 12 mg High dose: 1000–12,000 mg/m^2 intravenously every 2–3 weeks	Nausea, vomiting, mucositis	Myelosuppression, nephrotoxicity, hepatotoxicity, neurotoxicity (with intrathecal administration and high-

			dose therapy), photosensitivity, pulmonary toxicity, caution multiple drug interactions which may enhance toxicities (avoid aspirin, penicillins, NSAIDs, omeprazole, TMP-SMZ)
Pemetrexed (Alimta)	500 mg/m^2 intravenously every 3 weeks	Fatigue, nausea, vomiting, diarrhea, rash	Myelosuppression, mucositis Avoid NSAIDs which may decrease pemetrexed clearance and

			enhance toxicities
Antimetabolites—Purine Analogs			
Cladribine (Leustatin)	0.14 mg/kg/d intravenously or subcutaneously daily for 5 days or 0.09 mg/kg/d intravenously via continuous infusion for 7 days	Mild nausea, fatigue, injection site reaction, rash	Myelosuppression, immunosuppression, fever
Clofarabine (Clolar)	52 mg/m^2 intravenously daily for 5 days every 2–6 weeks (for patients < 21 years of age)	Nausea, vomiting, diarrhea, dermatitis, pruritus, headache, rigor	Myelosuppression, hepatotoxicity, nephrotoxicity, capillary leak syndrome, immunosuppression
Fludarabine (Fludara)	25 mg/m^2 intravenously for 5 days every 4 weeks	Asthenia, fever, myalgias, rare hypersensitivity	Myelosuppression, immunosuppression, neurotoxicity, visual

		reaction	disturbances
Mercaptopurine (6-MP; Purinethol)	Induction: 2.5–5 mg/kg/d orallyMaintenance: 1.5–2.5 mg/kg/d orally	Diarrhea, hyperpigmentation of skin, rash	Myelosuppression, immunosuppression, hepatotoxicity, mucositis
Pentostatin (Nipent)	4 mg/m^2 intravenously every other week	Nausea, vomiting, rash	Myelosuppression, immunosuppression, hepatotoxicity
Antimetabolites—Pyrimidine Analogs			
Azacitidine (Vidaza)	75 mg/m^2 subcutaneously or intravenously for 7 days every 4 weeks, may increase to 100 mg/m^2 after two cycles if no response	Injection site reaction, nausea, constipation, fever	Myelosuppression, hepatotoxicity, and nephrotoxicity (rare)
Capecitabine	625–1250 mg/m^2 orally twice a day	Nausea, vomiting,	Hand-foot syndrome,

(Xeloda)	for 14 days every 3 weeks	diarrhea	mucositis, hyperbilirubinemia, myelosuppression
Cytarabine (Ara-C, Cytosar U)	Standard dose: 100 mg/m^2/d intravenously via continuous infusion for 7 daysHigh dose: 1000–3000 mg/m^2 intravenously every 12 hours on days 1, 3, 5	Nausea, vomiting, rash, flu-like syndrome	Myelosuppression High-dose therapy: neurotoxicity (cerebellar ataxia, lethargy, confusion), ocular toxicities (conjunctivitis and keratitis), hepatotoxicity, pancreatitis, pulmonary toxicity
Cytarabine Liposome	50 mg intrathecally every		Chemical arachnoiditis

(DepoCyt)	14 or 28 days		
Decitabine (Dacogen)	15 mg/m^2 intravenously every 8 hours for 3 days, repeat every 8 weeks	Nausea, fatigue, hyperglycemia	Myelosuppression
Fluorouracil (5-FU; Adrucil)	500–600 mg/m^2 intravenous bolus weekly for 6 weeks, repeat every 8 weeks; in combination with oxaliplatin: 400 mg/m^2 intravenous bolus followed immediately by 600 mg/m^2 intravenously over 22 hours on days 1 and 2 or 400 mg/m^2 intravenous bolus followed immediately by 2400 mg/m^2	Nausea, diarrhea	Myelosuppression (intravenous bolus), hand-foot syndrome, mucositis, neurotoxicity, ocular toxicity, photosensitivity, cardiotoxicity (rare)

	intravenously over 46 hours; 1000 mg/m^2 intravenously via continuous infusion for 4–5 days every 3–4 weeks		
Gemcitabine (Gemzar)	1000–1250 mg/m^2 intravenously on days 1, 8, 15 every 4 weeks	Nausea, rash, flu-like symptoms, fever, diarrhea	Myelosuppression, edema, hepatotoxicity (rare), hemolytic uremic syndrome (rare), pulmonary toxicity (rare)
Antimicrotubules—Vinca Alkaloids			
Vinblastine (Velban)	6 mg/m^2 intravenously on days 1 and 15 every 4 weeks; 0.11 mg/kg on days 1 and 2	Vesicant, bronchospasm and dyspnea (rare)	Myelosuppression, peripheral neuropathy, constipation, mucositis,

			alopecia, SIADH (rare)
Vincristine (Oncovin)	0.5–1.4 mg/m^2 intravenously every 3 weeks; 0.4 mg/m^2 intravenously via continuous infusion for 4 days; maximum single dose usually limited to 2 mg	Vesicant	Peripheral neuropathy, constipation, alopecia, SIADH (rare)
Vinorelbine (Navelbine)	30 mg/m^2 intravenously on days 1 and 8 every 3 weeks	Vesicant, nausea, vomiting, bronchospasm and dyspnea (rare)	Myelosuppression, peripheral neuropathy, constipation, alopecia, SIADH (rare)
Antimicrotubules—Taxanes			
Docetaxel (Taxotere)	60–100 mg/m^2 intravenously every 3 weeks;	Hypersensitivity reaction,	Myelosuppression, peripheral

	35–40 mg/m^2 intravenously weekly for 3 weeks with 1 week rest	nausea, vomiting	neuropathy, alopecia, edema, fatigue, mucositis, diarrhea
Paclitaxel (Taxol)	135–175 mg/m^2 intravenously every 3 weeks; 50–80 mg/m^2 intravenously weekly	Hypersensitivity reaction, nausea, vomiting, bradycardia and hypotension during infusion	Myelosuppression, peripheral neuropathy, alopecia, mucositis, diarrhea, arthralgias/myalgias
Paclitaxel protein-bound (Abraxane)	260 mg/m^2 intravenously every 3 weeks	Nausea, vomiting, diarrhea, hypersensitivity reaction (less than paclitaxel)	Myelosuppression, peripheral neuropathy, alopecia, mucositis, arthralgias/myalgias
Antimicrotubules—Epothilone			
Ixabepilone (Ixempra)	40 mg/m^2 intravenously	Hypersensitivity	Peripheral neuropathy,

	every 3 weeks	reaction, nausea, vomiting	myelosuppression, alopecia, fatigue, mucositis, diarrhea, arthralgias/ myalgias
Enzyme Inhibitors—Anthracyclines			
Daunorubicin (Cerubidine)	30–60 mg/m^2 intravenously for 3 days	Nausea, vomiting, mucositis, diarrhea, red/orange discoloration of urine, cardiotoxicity (ECG changes). - All anthracyclines except for liposomal doxorubici	Myelosuppression, cardiotoxicity (cardiomyopathy with congestive heart failure–dose related), alopecia. - Liposomal Doxorubicin can also cause hand-foot syndrome
Liposomal Daunorubicin (Daunoxome)	40 mg/m^2 intravenously every 2 weeks		
Doxorubicin (Adriamycin)	15–20 mg/m^2 intravenously weekly; 45–60 mg/m^2 intravenously every 3 weeks		
Liposomal	20–50 mg/m^2		

Doxorubicin (Doxil)	intravenously every 3–4 weeks	n are potent vesicants. - Liposomal daunorubicin and liposomal doxorubicin may cause infusion-related reactions	
Epirubicin (Ellence)	35 mg/m^2 intravenously every 2 weeks; 60–120 mg/m^2 intravenously every 3–4 weeks		
Idarubicin (Idamycin)	12 mg/m^2 intravenously for 3 days		
Enzyme Inhibitors—Topoisomerase Inhibitors			
Etoposide (Vepesid)	50–100 mg/m^2 intravenously for 3–5 days every 3 weeks, oral dose is twice the intravenous dose	Nausea, vomiting, hypersensitivity reaction, fever, hypotension	Myelosuppression, alopecia, fatigue
Etoposide Phosphate (Etopophos	100 mg/m^2 intravenously for 3–5 days every 3		

)	weeks		
Irinotecan (Camptosar)	60 mg/m^2 intravenously on days 1, 8, and 15 every 4 weeks; 125 mg/m^2 intravenously weekly for 4 weeks every 6 weeks; 180 mg/m^2 intravenously every other week; 350 mg/m^2 intravenously every 3 weeks	Diarrhea and cholinergic syndrome, nausea, vomiting	Myelosuppression, alopecia
Topotecan (Hycamtin)	1.5 mg/m^2 intravenously for 5 days every 3 weeks; 2.3 mg/m^2 orally for 5 days every 3 weeks	Nausea, vomiting, diarrhea	Myelosuppression, alopecia, asthenia
Targeted Therapy—Monoclonal Antibodies			
Alemtuzumab	30 mg/m^2 intravenously	Infusion-related	Myelosuppression,

(Campath)	three times weekly	reaction, nausea, vomiting, hypotension	immunosuppression
Bevacizumab (Avastin)	5–15 mg/kg intravenously every 2–3 weeks	Infusion-related reaction	Arterial thromboembolism, wound healing complications, gastrointestinal perforation or fistula, hemorrhage, hypertension, proteinuria
Cetuximab (Erbitux)	Loading dose 400 mg/m^2 intravenously followed by maintenance dose 250 mg/m^2 intravenously weekly	Infusion-related reaction	Acneiform skin rash, hypomagnesemia, asthenia, paronychial inflammation, pulmonary toxicity (rare)

Gemtuzumab ozogamicin (Mylotarg)	9 mg/m^2 intravenously	Infusion-related reaction, nausea, vomiting	Myelosuppression, hepatotoxicity, veno-occlusive disease (rare)
Ibritumomab tiuxetan (Zevalin)	0.4 mCi/kg intravenously on day 8	Infusion-related reaction	Myelosuppression, asthenia, infections, increased risk of secondary malignancies
^{131}I Tositumomab (Bexxar)	450 mg intravenously	Infusion-related reaction	Myelosuppression, asthenia, infections, hypothyroidism, increased risk of secondary malignancies
Panitumumab (Vectibix)	6 mg/kg intravenously every 2 weeks	Infusion-related reaction	Acneiform skin rash, hypomagnesemia,

			asthenia, paronychial inflammation, pulmonary toxicity (rare)
Rituximab (Rituxan)	375 mg/m^2 intravenously weekly for 4 weeks, or every 3 weeks	Infusion-related reaction	Rare reactions: Hepatitis B reactivation, pulmonary toxicity, tumor lysis syndrome, Stevens-Johnson syndrome, progressive multifocal leukoencephalopathy, cardiac arrhythmias, bowel obstruction
Trastuzumab	Loading dose 4 mg/kg	Infusion-related	Cardiotoxicity, pulmonary

(Herceptin)	intravenously followed by 2 mg/kg intravenously weekly; or loading dose 8 mg/kg followed by 6 mg/kg intravenously every 3 weekly	reaction, headache, diarrhea	toxicity, myelosuppression in combination with chemotherapy
Targeted Therapy—Tyrosine Kinase Inhibitors			
Dasatinib (Sprycel)	70 mg orally twice daily; 100–140 mg orally once daily	Diarrhea, nausea, vomiting	Myelosuppression, fluid retention, fatigue, musculoskeletal pain, rash, cardiac dysfunction/congestive heart failure (rare), hemorrhage (rare)
Erlotinib (Tarceva)	100–150 mg orally once daily	Diarrhea	Acneiform skin rash, fatigue,

			anorexia, conjunctivitis, gastrointestinal hemorrhage (rare), pulmonary toxicity (rare)
Gefitinib (Iressa)	250 mg orally once daily	Diarrhea	Acneiform skin rash, asthenia, ocular toxicity, myelosuppression, hepatotoxicity (rare), pulmonary toxicity (rare)
Imatinib (Gleevec)	100–800 mg orally once daily	Nausea, vomiting, diarrhea	Myelosuppression, edema, myalgias, rash, congestive

			heart failure, left ventricular dysfunction (rare), hemorrhage (rare), hepatotoxicity (rare)
Lapatinib (Tykerb)	1250 mg orally once daily in combination with capecitabine	Diarrhea, nausea, vomiting	Hand-foot syndrome, fatigue, hepatotoxicity (rare), left ventricular dysfunction (rare), prolonged QT interval (rare), interstitial lung disease (rare)
Nilotinib (Tasigna)	400 mg orally twice daily	Nausea, vomiting, headache, diarrhea	Edema, rash, arthralgia, fatigue, myelosuppre

			ssion, electrolyte abnormalities, elevated serum lipase (rare), hepatotoxicity (rare), prolonged QT interval (rare)
Sorafenib (Nexavar)	400 mg orally twice daily	Diarrhea and nausea	Hypertension, hand-foot syndrome, rash, fatigue, gastrointestinal perforation (rare), hemorrhage (rare), cardiac ischemia/infarction (rare)
Sunitinib (Sutent)	50 mg orally once daily for 4 weeks followed by 2 weeks rest.	Diarrhea and nausea	Hypertension, hand-foot syndrome, rash, yellow

			discoloration of skin, fatigue, hypothyroidism, mucositis, myelosuppression, left ventricular dysfunction (rare), prolonged QT interval (rare), hemorrhage (rare)
Miscellaneous Agents			
Altretamine (Hexalen)	260 mg/m^2 orally in 4 divided doses for 14–21 days every 4 weeks	Nausea, vomiting, diarrhea	Neurotoxicity, myelosuppression, flu-like syndrome
Arsenic Trioxide (Trisenox)	0.15 mg/kg intravenously daily	Nausea, dizziness	Edema, acute promyelocytic leukemia differentiation syndrome

			(fever, dyspnea, skin rash, fluid retention, pleural effusions), prolonged QT interval and complete atrioventricular block
Asparaginase (Elspar)	6000–10,000 units/m^2 intravenously daily on days 17–28; 6000–10,000 units/m^2 intramuscularly every 3 days for a total of 9 doses	Hypersensitivity reaction (requires test dose), nausea, vomiting	Coagulation abnormalities (hemorrhagic and/or thrombotic events), hepatotoxicity, pancreatitis, neurotoxicity
Bleomycin (Blenoxane)	10 units/m^2 intravenously on days 1 and 15 every 4 weeks; 30 units on day 2, 9, and 16 every 3	Hypersensitivity reaction	Skin reaction (rash, hyperpigmentation of skin, striae), pulmonary

	weeks		fibrosis
Bortezomib (Velcade)	1.3 mg/m^2 intravenous bolus on days 1, 4, 8, 11 followed by a 10 day rest every 3 weeks	Orthostatic hypotension, fever	Peripheral neuropathy, fatigue, myelosuppression, hemorrhage (rare), left ventricular dysfunction (rare), pulmonary toxicity (rare), reversible posterior leukoencephalopathy syndrome (rare), hepatotoxicity (rare)
Dactinomycin (Cosmegen)	15 mcg/kg intravenously daily for 5 days; 12 mcg/kg	Vesicant, nausea, vomiting	Myelosuppression, mucositis, diarrhea,

	intravenously daily for 5 days; 1000 mcg/m^2 intravenously		alopecia, hyperpigmentation of skin, hepatotoxicity, hepato-veno-occlusive disease (rare)
Denileukin diftitox (Ontak)	9 or 18 mcg/kg intravenously daily for 5 days every 3 weeks	Flu-like syndrome, hypersensitivity reaction, nausea, vomiting	Diarrhea, decreased visual acuity, fever, increased risk for infection, hypoalbuminemia, capillary leak syndrome (rare)
Hydroxyurea (Hydrea)	20–30 mg/kg orally once daily	Nausea	Myelosuppression, dermopathy
Lenalidomide (Revlimid)	5–25 mg orally once daily for 21 days every 4	Diarrhea, itching, rash	Myelosuppression, potential for

	weeks		birth defects, thromboembolic events, fatigue
Mitomycin (Mutamycin)	20 mg/m^2 intravenously every 6–8 weeks; 20–40 mg intravesically weekly	Vesicant, local irritation (cystitis when given intravesically)	Myelosuppression, mucositis, hemolytic uremic syndrome (rare), pulmonary toxicity (rare)
Mitoxantrone (Novantrone)	12–14 mg/m^2 intravenously every 3 weeks; induction chemotherapy for leukemia 12 mg/m^2 intravenously for 2–3 days	Blue-green discoloration of urine, nausea, vomiting, diarrhea, intravenous irritant	Myelosuppression, cardiotoxicity, alopecia, mucositis, increased risk of secondary malignancies (rare)
Temsirolimus (Torisel)	25 mg intravenously weekly	Hypersensitivity reaction,	Myelosuppression, edema, fatigue,

		rash	mucositis, hyperglycemia, hyperlipemia, immunosuppression, nephrotoxicity, interstitial lung disease (rare), bowel perforation (rare), abnormal wound healing
Thalidomide (Thalomid)	50–800 mg orally once daily	Sedation, constipation, fatigue	Potential for birth defects, thromboembolic events, peripheral neuropathy, edema
Tretinoin (All-Trans-Retinoic Acid,	45 mg/m^2 orally divided twice daily for 45–90 days or 30 days		Headache, vitamin A toxicity, retinoic acid-

ATRA, Vesanoid)	past complete remission		acute promyelocytic leukemia syndrome, ototoxicity
Antiandrogens			
Bicalutamide (Casodex)	50 mg orally once daily	None	Hot flashes, decreased libido, impotence, gynecomastia, breast tenderness, fatigue
Flutamide (Eulexin)	250 mg orally every 8 hours	Diarrhea, yellow-green discoloration of urine	Hot flashes, decreased libido, impotence, gynecomastia, breast tenderness, hepatotoxicity (rare)
Nilutamide (Nilandron)	300 mg orally for 30 days then 150 mg orally once daily	Nausea	Visual disturbances (impaired adaptation to

			dark), hot flashes, decreased libido, impotence, gynecomastia, breast tenderness, disulfiram reaction with alcohol, interstitial pneumonitis (rare), hepatotoxicity (rare)
Selective Estrogen Receptor Modulators			
Tamoxifen (Nolvadex)	20–40 mg orally once daily	None	Hot flashes, vaginal discharge or bleeding, menstrual irregularities, thromboembolic events (rare), endometrial

			hyperplasia, cataracts, hepatotoxicity, tumor flare
Toremifene (Fareston)	60 mg orally once daily	Nausea	Hot flashes, vaginal discharge, thromboembolic events (rare), tumor flare, endometrial hyperplasia, cataracts, hepatotoxicity
Aromatase Inhibitors			
Anastrozole (Arimidex)	1 mg orally once daily	Nausea	Hot flashes, peripheral edema, hypercholesterolemia, arthralgia/myalgia, headache, osteoporosis
Exemestane (Aromasin)	25 mg orally once daily		
Letrozole (Femara)	2.5 mg orally once daily		
Pure Estrogen Receptor Antagonist			

Fulvestrant (Faslodex)	250 mg intramuscularly once a month	Injection site reactions, nausea, diarrhea, constipation	Hot flashes, backache, headache
Progestins			
Megestrol acetate (Megace)	40–320 mg orally once daily or in divided doses (four times a day)	Nausea	Hot flashes, tumor flare, weight gain, hyperglycemia, thrombotic events (rare), adrenal insufficiency (rare)
LHRH Analogs			
Goserelin acetate (Zoladex)	3.6 mg subcutaneously once every month; 10.8 mg subcutaneously once every 3 months	Injection site discomfort	Hot flashes, tumor flare, decreased libido, impotence, vaginal bleeding, thromboembolic events

			(rare), osteoporosis (rare)
Leuprolide (Lupron)	7.5 mg intramuscularly once every month; 22.5 mg intramuscularly once every 3 months; 30 mg intramuscularly once every 4 months	Injection site reaction	Hot flashes, tumor flare, edema, impotence, thromboembolic events (rare), osteoporosis
Triptorelin pamoate (Trelstar)	3.75 mg intramuscularly once every month; 11.25 mg intramuscularly once every 3 months	None	Hot flashes, tumor flare, skeletal pain, impotence
Adrenocorticosteroids			
Dexamethasone	40 mg orally once weekly or 40 mg orally on days 1–4, 9–12, 17–20	None	Hyperglycemia, weight gain, fluid retention, psychiatric symptoms

Ketoconazole	400 mg orally three times daily	Nausea and vomiting	Hepatotoxicity (rare)
Prednisone	5 mg orally twice a day; 100 mg orally daily for 5 days	None	Hyperglycemia, weight gain, gastritis, fluid retention, psychiatric symptoms
Biologic Response Modifiers			
Interferon- -2b (Intron A)	5 million international units subcutaneously 3 times a week; 2 million international units/m^2 intramuscularly/subcutaneously three times a week; 20 million international units/m^2 5 days a week for 4 weeks then 10 million	Hypersensitivity reaction, injection site reaction, flu-like syndrome, nausea, vomiting, diarrhea	Myelosuppression, fatigue, anorexia, alopecia, depression, hyperthyroidism or hypothyroidism (rare), hepatotoxicity (rare), visual disturbances

	international units/m^2 three times a week		
Aldesleukin (IL-2, Proleukin)	600,000 international units/kg intravenously every 8 hours for 14 doses, repeat after 9 days rest	Hypotension, nausea, vomiting, diarrhea	Capillary leak syndrome (rare), impaired neutrophil function and increased risk of infection, lethargy or somnolence that may result in coma if therapy is not held

GFR, glomerular filtration rate; LHRH, luteinizing hormone–releasing hormone; MAO, monoamine oxidase; NSAIDs, nonsteroidal anti-inflammatory drugs; SIADH, syndrome of inappropriate antidiuretic hormone; TMP-SMZ, trimethoprim-sulfamethoxazole.

Table 39–11. Supportive care agents: Dosage and toxicity.				
Agent	**Indication**	**Usual Dose**	**Acute Toxicity**	**Delayed Toxicity**
Allopurinol (Xyloprim)	Prevent hyperuricemia from tumor lysis syndrome	300 mg orally once daily	None	Rash, Stevens-Johnson syndrome (rare), myelosuppression (rare)
Rasburicase (Elitek)	Prevent hyperuricemia from tumor lysis syndrome	0.17–0.17 mg/kg intravenously for pediatric patients; 3–6 mg intravenously once	Hypersensitivity reaction in patients with G6PD deficiency, nausea, vomiting, diarrhea, fever, headache	Rash
Mesna	Prevent	20% of	Nausea	Fatigue,

(Mesnex)	ifosfamide-induced hemorrhagic cystitis	ifosfamide dose intravenously immediately before ifosfamide and at 4 hours and 8 hours after (total dose is 60% of ifosfamide dose); 100% of ifosfamide dose mixed with ifosfamide in same intravenous bag	and vomiting	hypotension
Leucovorin	Rescue after high-dose methotrexate; in	10 mg/m^2 intravenously or orally every 6 hours until	Nausea	None

	combination with fluorouracil for colon cancer	serum methotrexate level is below 0.01 micromolar; 20 mg/m^2 or 200–500 mg/m^2 intravenously before fluorouracil		
Amifostine (Ethyol)	Prevent cisplatin nephropathy; prevent radiation-induced xerostomia	910 mg/m^2 intravenously before cisplatin; 200 mg/m^2 intravenously before radiation	Nausea, vomiting, hypotension, infusion-related reaction	Hypocalcemia
Dexrazoxane (ZInecard)	Prevent cardiomyopathy secondary to doxorubici	10 times the doxorubicin dose intravenously before	Nausea	Myelosuppression

	n; anthracycline-induced injection site extravasation	doxorubicin		
Palifermin (Kepivance)	Prevent mucositis following chemotherapy	60 mcg/kg/d intravenously for 3 days before and 3 days after chemotherapy	None	Edema, rash, pruritus, erythema, fever, enlargement or discoloration of tongue, altered taste sensation
Pilocarpine (Salagen)	Radiation-induced xerostomia	5 mg orally 1 hour before chemotherapy, then 5 mg once daily for 7	Flushing, sweating, nausea, dizziness, increased urinary frequency	None

		days; 5–10 mg orally three times a day	, rhinitis	
Samarium (Quadramet)	Pain from bone metastasis	1 milliCurie/kg intravenously	Pain flare, diarrhea, hematuria	Myelosuppression, spinal cord compression
Strontium (Metastron)	Pain from bone metastasis	148 megabecquerels (4 milliCuries) intravenously; or 1.5–2.2 megabecquerels/kg (40–60 microcuries/kg)	Flushing, pain flare	Myelosuppression
Pamidronate (Aredia)	Osteolytic bone metastasis, hypercalcemia of malignanc	90 mg intravenously every 3–4 weeks; 60–90 mg intravenous	Injection site reaction	Electrolyte disturbances (hypocalcemia), anemia,

	y	ly, may repeat after 7 days		arthralgia, bone pain, osteonecrosis of the jaw, nephrotoxicity
Zoledronic acid (Zometa)	Osteolytic bone metastasis, hypercalcemia of malignancy	4 mg intravenously every 3–4 weeks	Injection site reaction	Electrolyte disturbances (hypocalcemia), anemia, arthralgia, bone pain, osteonecrosis of the jaw, nephrotoxicity
Growth Factors				
Epoetin alfa (Epogen, Procrit)	Chemotherapy-induced anemia	40,000 units subcutaneously once weekly; 150	Injection site reaction	Hypertension, thrombotic events, increased risk of

		units/kg subcutaneously 3 times a week		tumor progression or recurrence, seizures, rash
Darbepoetin alfa (Aranesp)	Chemotherapy-induced anemia	2.25 mcg/kg subcutaneously weekly; 500 mcg subcutaneously every 3 weeks	Injection site reaction	Hypertension, thrombotic events, increased risk of tumor progression or recurrence, seizures, rash
		Alternative dosing: 200 mcg subcutaneously every 2 weeks or 300 mcg subcutaneously every 3 weeks		
Filgrastim	Febrile neutropeni	5–10 mcg/kg/d	Injection site	Bone pain, enlarged

(Neupogen)	a prophylaxis	subcutaneously or intravenously once daily, treat past nadir	reaction	spleen, leukocytosis
Pegfilgrastim (Neulasta)	Febrile neutropenia prophylaxis	6 mg subcutaneously once per chemotherapy cycle	Injection site reaction	Bone pain, enlarged spleen, leukocytosis
Sargramostim (Leukine)	Myeloid reconstitution following bone marrow transplant, febrile neutropenia prophylaxis	250 mcg/m^2 intravenously daily until the absolute neutrophil count is greater than 1500 cells/mcL for 3 consecutive days	Rash, pruritus, injection site reaction, dyspnea, fever	Bone pain, myalgia, fluid retention, supraventricular tachycardia, capillary leak syndrome (rare)
Oprelve	Chemother	50 mcg/kg	Nausea,	Candidiasis

kin (Neumega)	apy-induced thrombocytopenia	subcutaneously every day for 14–21 days or until post-nadir platelet count is greater than 50,000/mcL	vomiting, headache, dizziness, blurred vision, dyspnea, injection site reaction	, rash, fluid retention, arrhythmias, febrile neutropenia

G6PD, glucose 6-phosphate dehydrogenase.

A complete blood count consisting of a differential count with particular attention to the absolute neutrophil count and platelet count as well as tests of liver and kidney function should be obtained before the initiation of chemotherapy. In patients with normal blood counts as well as normal liver and kidney function, drugs are started at their full dose. When the intent of chemotherapy is cure, including treatment in the adjuvant setting, every attempt should be made to schedule chemotherapy on time and at full dose. A complete blood count with differential should be checked at mid cycle to determine the nadir of the absolute neutrophil and platelet counts as well as immediately before the next cycle of chemotherapy is due.

Dose reductions may be necessary for patients with impaired kidney or liver function depending on the clearance mechanism of the drug. For patients receiving chemotherapy for palliation, bone marrow toxicity can be managed with dose reductions or delaying the next treatment cycle. A schema for dose modification is shown in Table 39–12.

Table 39–12. A common scheme for dose modification of cancer chemotherapeutic agents.

Granulocyte Count (cells/mcL)	**Platelet Count (/mcL)**	**Suggested Drug Dosage (% of Full Dose)**
> 2000	> 100,000	100%
1000–2000	75,000–100,000	50%
< 2000	< 50,000	0%

Bone Marrow Toxicity

Depression of the bone marrow and the ability to produce adequate numbers of white cells, red cells, and platelets is usually the most significant limiting toxicity with cancer chemotherapy. Drugs to ameliorate bone marrow suppression have become standard tools in the armamentarium of medical oncologists.

Neutropenia

Granulocyte colony-stimulating factor (G-CSF), given as either daily subcutaneous injections (filgrastrim, 300 mcg or 480 mcg) or as a one-time dose (pegfilgrastim, 6 mg) beginning 24–72 hours after cytotoxic chemotherapy is completed, has been shown to markedly reduce the duration and severity of granulocytopenia following cytotoxic chemotherapy (Table 39–11). The American Society of Clinical Oncology and NCCN guidelines recommend primary prophylaxis with a G-CSF when there is 20% risk of febrile neutropenia or when the patient's age, medical history, and disease characteristics makes the patient at high risk for complications related to myelosuppression.

Anemia

Erythropoiesis-stimulating agents (ESAs) have been shown to ameliorate the anemia and associated symptoms caused by cancer chemotherapy. However, the evidence suggests that these drugs have untoward effects, including an increased risk of thromboembolism, and even more concerning, decreased survival due to cancer-related deaths. These findings have prompted the US Food and Drug Administration and other organizations (American Society of Hematology, American Society of Clinical Oncology, and NCCN) to issue advisories and guidelines limiting their use. The recommendation that these drugs should not be used when the intent of chemotherapy is curative is controversial, although the evidence is mounting that survival is indeed adversely affected by the administration of ESAs. Studies done in patients with potentially curable head and neck, breast, and cervical cancers have shown inferior outcomes when ESAs were used, though the target hemoglobin for patients in these studies was higher than what is currently recommended. The alternative to managing symptomatic anemia in these patients receiving curative chemotherapy is administration of red blood cell transfusions.

Although the details of these recommendations vary, all agree that oncologists should use ESAs in anemic patients receiving chemotherapy and generally should not be given until the hemoglobin is less than 10 g/dL with the medication held when the hemoglobin is greater than 12 g/dL. Epoetin alfa can be given subcutaneously as a weekly dose of 30,000–40,000 units with a target hemoglobin of 11–12 g/dL (see Table 39–11). Darbepoetin alfa is given subcutaneously every 2–3 weeks at a dose of 200–300 mcg with the same target hemoglobin. Patients need to be iron replete to have maximum therapeutic effect. Uncontrolled hypertension is a contraindication to the use of ESAs; blood pressure must be controlled prior to initiation of this therapy.

Thrombocytopenia

Drug management of chemotherapy-induced thrombocytopenia is more limited. The only available drug, oprelvekin or recombinant interleukin-11, has modest activity in improving thrombocytopenia associated with chemotherapy; however, the side effects of fluid retention, congestive heart failure, and arrhythmias have limited its use. Thrombopoietin, the protein that stimulates megakaryopoieis in vivo, was isolated in 1994. Despite much work attempting to produce a clinically effective thrombopoietin drug for therapeutic use, no such drug is commercially available for this indication. Two drugs approved for use in idiopathic thrombocytopenia romiplostim and eltrombopag have not been shown to benefit patients with chemotherapy-associated thrombocytopenia.

Chemotherapy-Induced Nausea & Vomiting

A number of cytotoxic anticancer drugs can induce nausea and vomiting, which can be the most anticipated and stressful side effects for patients. Chemotherapy-induced nausea and vomiting is mediated in part by the stimulation of at least two central nervous system receptors, 5-hydroxytryptamine subtype 3 ($5HT_3$) and neurokinin subtype 1 (NK_1). Chemotherapy-induced nausea and vomiting can be acute, occurring within minutes to hours of chemotherapy administration, or delayed until the second day and lasting up to 7 days.

Anticipatory nausea and vomiting may even occur before the administration of chemotherapy. Chemotherapy drugs or drug regimens are classified into high, moderate, low, and minimal likelihoods of causing emesis (90%, 30–90%, 10–30%, < 10%, respectively). Highly emetogenic chemotherapy drugs include cisplatin, carmustine, cyclophosphamide at doses over 1.5 g/m^2, dacarbazine, mechlorethamine, and streptozocin. Chemotherapy drugs that are moderately emetogenic include doxorubicin, daunomycin, idarubicin, epirubicin, cyclophosphamide, irinotecan, oxaliplatin, ifosfamide, cytarabine, and carboplatin. Drugs with low emetic potential include bortezomib, docetaxel, etoposide, fluorouracil, gemcitabine, methotrexate, mitomycin, mitoxantrone, paclitaxel, pemetrexed, temsirolimus, and topotecan. Drugs with minimal risk of emesis include bevacizumab, bleomycin, cladribine, fludarabine, vinblastine, vincristine, and vinorelbine.

By understanding the physiology of chemotherapy-induced nausea and vomiting, major advances have occurred with the development of new, highly effective antiemetic drugs. Antagonists to the 5HT$_3$-receptor include ondansetron, granisetron, dolasetron, tropisetron, and palonosetron. Each of these drugs have similar efficacy. Ondansetron can be given either intravenously (8 or 0.15 mg/kg) or orally (24 mg for highly emetogenic chemotherapy, 8 mg twice daily for moderately emetogenic chemotherapy). Doses of 8 mg can be repeated parenterally or orally every 8 hours. Dosing of granisetron is 1 mg or 0.01 mg/kg intravenously or 1–2 mg orally. Dolasetron is given 1.8 mg/kg or a fixed dose of 100 mg intravenously or 100 mg can be given orally. Tropisetron is given at a dose of 5 mg either orally or intravenously. Palonosetron, a long-acting $5HT_3$ with high affinity for the $5HT_3$-receptor given at a dose of 0.25 mg intravenously, is effective for not only acute but also delayed emesis. The efficacy of the $5HT_3$-blockers is improved by adding 6–10 mg of either oral or intravenous dexamethasone.

Aprepitant is an antagonist to the NK_1 receptor. When given as a 125-mg oral dose followed by 80 mg on the second and third day with a $5HT_3$-receptor antagonist (such as ondansetron or granisetron), the immediate and delayed protective effect for highly emetogenic chemotherapy is increased.

Standard therapy for highly emetogenic chemotherapy includes a $5HT_3$-antagonist given on the first day and both dexamethasone and aprepitant given on the first day as well as the second and third days. Moderately emetogenic chemotherapy regimens are best managed with a two-drug regimen of a $5HT_3$-antagonist and dexamethasone. Doses of the $5HT_3$ may be given on days 2 and 3 to prevent delayed emesis.

Other adjunctive medications that may be helpful include lorazepam, 0.5–1.0 mg given orally every 6–8 hours, and prochlorperazine, 5–10 mg orally or intravenously every 8 hours. Lorazepam, in addition to antianxiety effects, has an antinausea effect. Prochlorperazine is generally sufficient to treat patients receiving low emetogenic chemotherapy. A suppository form of prochlorperazine, 25 mg, may be used for patients who are unable to swallow oral medications.

The importance of treating chemotherapy-induced nausea and vomiting expectantly and aggressively beginning with the first course of chemotherapy cannot be understated. Patients being treated in the clinic setting should always be given antiemetics for home use with written instructions as well as contact numbers to call for advice.

Gastrointestinal Toxicity

Untoward effects of cancer chemotherapy include damage to the more rapidly growing cells of the body such as the mucosal lining from the mouth through the gastrointestinal tract. Oral symptoms range from mild mouth soreness to frank ulcerations in the mouth. Not uncommonly, mouth ulcerations will have superimposed candida or herpes simplex infections. In addition to receiving cytotoxic chemotherapy, a significant risk factor for development of oral mucositis is poor oral hygiene and existing caries or periodontal disease. Toxicity in the gastrointestinal tract usually manifests as diarrhea. Gastrointestinal symptoms can range from mild symptoms of loose stools to life-threatening diarrhea due to dehydration and electrolyte imbalances. Drugs most commonly associated with causing mucositis in the mouth and the gastrointestinal tract are cytarabine, 5-fluorouracil, and methotrexate.

Patients undergoing treatment for head and neck cancer with concurrent chemotherapy and radiation therapy have a very high risk of developing severe mucositis.

Preventive strategies for managing oral mucositis includes a pretreatment dental examination, particularly for all head and neck cancer patients and any cancer patient with poor dental hygiene who will be receiving chemotherapy. For patients receiving fluorouracil, simple measures such as ice chips in the mouth for 30 minutes during infusion can reduce the incidence and severity of mucositis. Once mucositis is encountered, superimposed fungal infections should be treated with topical antifungal medications (oral nystatin mouth suspensions, or clotrimazole troches) or systemic therapy (fluconazole 100–400 mg orally daily). Suspected herpetic infections can be treated with acyclovir (up to 800 mg orally five times daily) or valacyclovir (1 g orally twice daily). Mucositis may also be managed with mouthwashes; it is also important to provide adequate pain medication.

Newer strategies for prevention of oral mucositis includes the recombinant keratinocyte growth factor inhibitor palifermin. Practice guidelines recommend its use in patients undergoing high-dose chemotherapy because when intravenous palifermin (60 mcg/kg/d) is given prophylactically to patients undergoing high-dose chemotherapy for hematologic diseases, both the incidence and length of mucositis is decreased.

Diarrhea is most associated with fluorouracil, capecitabine, and irinotecan as well as the tyrosine kinase inhibitors (sorafenib, sunitinib, imatinib, dasatinib) and epithelial growth factor inhibitors (cetuximab, panitumumab, and erlotinib). Mild to moderate diarrhea can be managed with oral antidiarrheal medication (loperamide, 4 mg initially followed by 2 mg every 2–4 hours until bowel movements are formed). Occasionally, the diarrhea will be overwhelming causing dehydration, electrolyte imbalances, and acute kidney injury. These patients require inpatient management with aggressive intravenous hydration and replacement of electrolytes.

Skin Toxicity

Dermatologic complications from cancer chemotherapy can include hyperpigmenation (liposomal doxorubicin, busulfan, hydroxyurea) alopecia, photosensitivity, nail changes, acral erythema, and generalized rashes. Acral erythema, otherwise known as hand-foot syndrome and most commonly associated with administration of fluorouracil, capecitabine, and liposmal doxorubicin, manifests as painful palms or soles accompanied by erythema, progressing to blistering desquamation and ulceration in its worst forms. Management can include attempts at prevention with oral pyridoxine, 200 mg daily, and applying cold packs to the extremities while the chemotherapy is being administered. The newer agents targeting the epidermal growth factor pathway can cause an acne like rash; interestingly, the development of the rash may identify those who will respond to the drug. Inhibitors of the tyrosine kinase pathway are also associated with a high incidence of dermatologic complications, such as rash and acral erythema.

Miscellaneous Drug-Specific Toxicities

The toxicities of individual drugs have been summarized in Tables 39–10 and 39–11; however, several of these warrant additional mention, since they occur with frequently administered agents, and special measures are often indicated.

Hemorrhagic Cystitis Induced by Cyclophosphamide or Ifosfamide

Metabolic products of cyclophosphamide that retain cytotoxic activity are excreted into the urine. Some patients appear to metabolize more of the drug to these active excretory products; if their urine is concentrated, severe bladder damage may result. Patients receiving cyclophosphamide must maintain a high fluid intake prior to and following the administration of the drug and be counseled to empty their bladders frequently. Early symptoms suggesting bladder toxicity include dysuria and increased frequency or urination. Should microscopic hematuria develop, it is advisable to stop the drug temporarily or switch to a different alkylating agent, to increase fluid intake, and to administer a urinary analgesic such as phenazopyridine. With severe cystitis, large segments of bladder mucosa may be shed, resulting in prolonged gross hematuria. Such patients should be observed for signs of urinary obstruction and may require cystoscopy for removal of obstructing blood clots. The cyclophosphamide analog ifosfamide can cause severe hemorrhagic cystitis when used alone. However, when its use is followed by a series of doses of the neutralizing agent mesna, bladder toxicity can be prevented. Mesna can also be used for patients taking cyclophosphamide in whom cystitis develops.

Neuropathy Due to Vinca Alkaloids and Other Chemotherapy Drugs

Neuropathy is caused by a number of different chemotherapy drugs, the most common being vincristine. The peripheral neuropathy can be sensory, motor, autonomic, or a combination of these effects. In its mildest form, it consists of paresthesias of the fingers and toes. Occasionally, acute jaw or throat pain can develop after vincristine therapy. This may be a form of trigeminal neuralgia. With continued vincristine therapy, the paresthesias extend to the proximal interphalangeal joints, hyporeflexia appears in the lower extremities, and significant weakness can develop. Other drugs in the vinca alkaloid class as well as the taxane drugs (paclitaxel and docetaxel) and the newer agents to treat myeloma (thalidomide and bortezomib) cause similar toxicity. The presence of neurologic symptoms is not in itself a reason to stop therapy; the severity of the symptoms must be balanced against the goals of therapy. Usually though, the presence of moderate to severe paresthesias or the detection of motor impairment would result in the decision to discontinue the drug.

Constipation is the most common symptom of autonomic neuropathy associated with the vinca alkaloids. Patients receiving these drugs should be started on stool softeners and mild cathartics when therapy is begun; otherwise, severe impaction may result from an atonic bowel.

More serious autonomic involvement can lead to acute intestinal obstruction with signs indistinguishable from those of an acute abdomen. Bladder neuropathies are uncommon but may be severe. These two complications are absolute contraindications to continued vincristine therapy.

C. Methotrexate Toxicity

Methotrexate, a folate antagonist, is a commonly used drug and a key component of regimens to treat patients with leptomeningeal disease, acute lymphoblastic leukemia, and sarcomas. The dose used in intrathecal therapy is 12 mg. Methotrexate is almost entirely eliminated by the kidney. The methotrexate toxicity affects cells with rapid turnover, including the bone marrow and mucosa resulting in myelosuppression and mucositis. Methotrexate can also damage the liver and kidney manifesting as elevated liver enzymes and creatinine. High-dose methotrexate, usually defined as a dose of 500 mg/m^2 or more given over 4–36 hours, would be lethal without "rescue" of the normal tissues. Leucovorin, a form of folate, will reverse the toxic effects of methotrexate and is given until serum methotrexate levels are in the safe range (less than 0.05 mmol/L). It is crucial that high-dose methotrexate and leucovorin are given precisely according to protocol as deviations of the timing of methotrexate delivery or delay in rescue can result in patient death. Lower doses of methotrexate can be problematic in patients with kidney disease who cannot clear the drug normally or with patients who have effusions. In the latter instance, methotrexate distributes itself in effusions and will leak out continuously, exposing normal tissue to small but cumulatively toxic amounts of the drug. If methotrexate is given to a patient who either has or develops kidney disease or to a patient with an effusion, prolonged rescue with leucovorin will be necessary.

Vigorous hydration and bicarbonate loading also appear to be important in preventing crystallization of high-dose methotrexate in the renal tubular epithelium and minimizing the possibility of nephrotoxicity. Daily monitoring of the serum creatinine is mandatory. Drugs impairing methotrexate excretion include aspirin, nonsteroidal anti-inflammatory drugs, amiodarone, omeprazole, penicillin, phenytoin, and sulfa compounds; these drugs should be stopped if possible before methotrexate administration.

Bleomycin Toxicity

Bleomycin is used for the treatment of testicular cancer, Hodgkin disease, and non-Hodgkin lymphoma. Bleomycin produces edema of the interphalangeal joints and hardening of the palmar and plantar skin. The more serious toxicities include an anaphylactic or serum sickness-like reaction and a serious or fatal pulmonary fibrotic reaction (seen especially in elderly patients receiving a total dose of over 300 units). If nonproductive cough, dyspnea, and pulmonary infiltrates develop, the drug is discontinued, and high-dose corticosteroids are instituted as well as empiric antibiotics pending cultures. Fever alone or with chills is an occasional complication of bleomycin treatment and is not an absolute contraindication to continued treatment. The fever may be avoided by intravenous premedication with hydrocortisone administration. Moreover, fever alone is not predictive of pulmonary toxicity. About 1% of patients (especially those with lymphoma) may have a severe or even fatal hypotensive reaction after the initial dose of bleomycin. In order to identify such patients, a test dose of 5 units of bleomycin is administered first with adequate monitoring and emergency facilities available should they be needed. Patients exhibiting a hypotensive reaction should not receive further bleomycin therapy.

Anthracycline Cardiotoxicity

A number of cancer chemotherapy drugs can cause cardiotoxicty. The most common class of drugs associated with cardiotoxicity is the anthracycline antibiotics, including doxorubicin, daunomycin, idarubicin, and epirubicin. They can produce acute (during administration), subacute (days to months following administration), and delayed (years following administration) cardiac toxicity. The most feared complication is the delayed development of congestive heart failure. Risk factors for this debilitating toxicity include the anthracycline cumulative dose, age over 70, previous or concurrent irradiation of the chest, preexisting cardiac disease, and concurrent administration of chemotherapy drugs such as trastuzumab. The problem is greatest with doxorubicin because this drug is the most commonly administered anthracycline due to its major role in the treatment of lymphomas, sarcomas, breast cancer, and certain other solid tumors. Patients receiving anthracyclines should have a baseline multiple-gated radionuclide cardiac scan (MUGA) to calculate the left ventricular ejection fraction (LVEF). If the LVEF is greater than 50%, anthracyclines can be administered; if the LVEF is less than 30%, these drugs should not be given. For patients with intermediate cardiac function, anthracycline dosing, if necessary, should be cautiously done with LVEF monitoring between doses. Studies of left ventricular function and endomyocardial biopsies indicate that some changes in cardiac dynamics occur in most patients by the time they have received 300 mg/m^2 of doxorubicin. In general, patients should not receive a total dose of doxorubicin in excess of 450 mg/m^2; the dose should be lower if prior chest radiotherapy has been given. The appearance of a high resting pulse may herald the appearance of overt cardiac toxicity. Unfortunately, toxicity may be irreversible and frequently fatal at dosage levels above 550 mg/m^2. At lower doses (eg, 350 mg/m^2 of doxorubicin), the symptoms and signs of cardiac failure generally respond well to medical therapy as well as the discontinuation of anthracycline. Laboratory studies suggest that cardiac toxicity may be due to a mechanism involving the formation of intracellular free radicals in cardiac muscle. The iron chelator dexrazoxane has been approved for use as a cardioprotectant for patients receiving anthracyclines; however, some evidence suggests that the anthracycline anticancer effect may be compromised by the coadministration of dexrazoxane. In general, dexrazoxane should not be used when the goal of chemotherapy is for curative intent either in the settings of adjuvant or definitive treatment. Doxorubicin and daunomycin have been formulated as liposomal products; these drugs, approved for use in patients with Kaposi sarcoma and sometimes used in certain cancers as a substitute for conventional anthracyclines, appear to have minimal potential for cardiac toxicity.

Cisplatin Nephrotoxicity and Neurotoxicity

Cisplatin is effective in treating a wide range of malignancies, including testicular, bladder, lung, and ovarian cancers. Although nausea and vomiting are the side effects most commonly associated with cisplatin, the more serious side effects of nephrotoxicity and neurotoxicity must also be anticipated and aggressively managed. Patients must be vigorously hydrated prior, during, and after cisplatin administration. Both kidney function and electrolytes must be monitored. Low magnesium and potassium levels as well as hyponatremia can develop. The neurotoxicity is usually manifested as a peripheral neuropathy of mixed sensorimotor type and may be associated with painful paresthesias. Development of neuropathy typically occurs after cumulative doses of 300 mg/m^2. Ototoxicity is a potentially serious manifestation of neurotoxicity and can progress to deafness. Amifostine, developed initially as a radioprotective agent and given intravenously at a dose of 910 mg/m^2 over 15 minutes prior to cisplatin, is used to protect against nephrotoxicity and neuropathy. Use of amifostine does not appear to compromise the antineoplastic effect of cisplatin. The second-generation platinum analog carboplatin is non-nephrotoxic, although it is myelosuppressive. In the setting of preexisting kidney disease or neuropathy, carboplatin is occasionally substituted for cisplatin.

Prognosis

A valuable sign of clinical improvement is the general well-being of the patient. Although this finding is a combination of subjective and objective factors and may be partly a placebo effect, it nonetheless serves as a sign of clinical improvement in assessing some of the objective observations listed above. Factors included in the assessment of general well-being are improved appetite and weight gain and increased "performance status" (eg, ambulatory versus bedridden). Evaluation of factors such as activity status enables the clinician to judge whether the net effect of chemotherapy is worthwhile palliation (see Chapter 5: Palliative Care & Pain Management).

Introduction to Medical Genetics

Physicians at one time concerned themselves only with what they could discover by bedside evaluation and laboratory investigation. In the parlance of genetics, the patient's symptoms and signs constitute his or her **phenotype**. Now the means are at hand for defining a person's **genotype**, the actual information content inscribed in the 2 m of coiled DNA present in each cell of the body—or half that amount in every mature ovum or sperm. Most phenotypic characteristics—and this includes diseases as well as human traits such as personality, adult height, and intelligence—are to some extent determined by the genes. The importance of the genetic contribution varies widely among human phenotypes, and methods are only now being developed to identify the genes involved in complex traits and most common diseases. Moreover, the importance of interactions between environment and genotype in producing phenotypes cannot be overstated despite the obscurity of the actual mechanisms.

The billions of nucleotides in the nucleus of a cell are organized linearly along the DNA double helix in functional units called **genes**, and each of the 20,000–25,000 human genes is accompanied by various regulatory elements that control when it is active in producing **messenger RNA (mRNA)** by a process called **transcription.** In most situations, mRNA is transported from the nucleus to the cytoplasm, where its genetic information is **translated** into **proteins**, which perform the functions that ultimately determine phenotype. For example, proteins serve as enzymes that facilitate metabolism and cell synthesis; as DNA binding elements that regulate transcription of other genes; as structural elements of cells and the extracellular matrix; and as receptor molecules for intracellular and intercellular communication. DNA also encodes many small RNA molecules that serve functions still being defined, including regulating gene transcription and interfering with the translational capacity of some mRNAs.

Chromosomes are the vehicles in which the genes are carried from generation to generation. Each chromosome is a complex of protein and nucleic acid in which an unbroken double helix of DNA is coiled and supercoiled into a space many orders of magnitude less than the extended length of the DNA. Within the chromosome there occur highly complicated and integrated processes, including DNA replication, recombination, and transcription. In the nucleus of each somatic cell, humans normally have 46 chromosomes, which are arranged in 23 pairs. One of these pairs, the **sex chromosomes** X and Y, determines the sex of the individual; females have the pair XX and males the pair XY. The remaining 22 pairs are called **autosomes** (Figure e2–1). In addition to these nuclear chromosomes, each mitochondrion—found in varying numbers in the cytoplasm of all cells—contains multiple copies of a small chromosome. This **mitochondrial chromosome** encodes a few of the proteins for oxidative metabolism and all of the transfer RNAs used in translation of proteins within this organelle. Mitochondrial chromosomes are inherited almost entirely from the cytoplasm of the fertilized ovum and are therefore maternal in origin.

Figure e2–1

Normal karyotype of a human male. Prepared from cultured amniotic cells and stained with Giemsa stain. About 400 bands are detectable per haploid set of chromosomes.

In all somatic cells, the 44 autosomes and one of the X chromosomes are transcriptionally active. In males, the active X is the only X; portions of the Y chromosome are also active. In females, the requirement for **dosage compensation** (to be equivalent to the situation in males) is satisfied by inactivation of most of one X chromosome early in embryogenesis. This process of X chromosomal inactivation, although incompletely understood, is known to be random, so that on average, in 50% of a female's cells, one of the X chromosomes will be active, and in the other 50% the **homologous** member of the pair will be active. The phenotype of the cell is determined by which genes on the chromosomes are active in producing mRNA at any given time.

Genes & Chromosomes

In all genes, information is contained in parcels called **exons**, which are interspersed with stretches of DNA called **introns** that do not encode any information about the protein sequence. However, introns may contain genetic regulatory sequences, and some introns are so large that they encode an entirely distinct gene.

The exact location of a gene on a chromosome is its **locus**, and the array of loci constitutes the **human gene map**. Currently, the chromosomal sites of more than 11,000 genes (for which normal or abnormal function has been identified) are known, often to a high degree of resolution. A variation of this map, identifying selected loci known to be involved in human disease, is shown in Figure e2–2. The difference in the higher resolution of the ordering of genes achievable by molecular techniques (such as linkage analysis) compared to cytogenetic techniques (such as visualization of small defects) is substantial, though the gap is narrowing. The chromosomes in the "standard" karyotype shown in Figure e2–1 have about 450 visible bands; under the best of cytologic and microscopic conditions, a total of about 1600 bands can be seen. But even in this extended configuration, each band contains dozens—sometimes hundreds—of individual genes. Thus, loss **(deletion)** of a small band will involve loss of many coding sequences and will have diverse effects on the phenotype.

Figure e2–2

A partial "morbid map" of the human genome. Shown next to the ideogram of the human X and Y chromosomes are representative mendelian disorders caused by mutations at that locus. Over 460 phenotypes have been mapped to the X chromosome and 8 to the Y chromosome.

(Courtesy of V. McKusick and J. Strayer.)

The number and arrangement of genes on homologous chromosomes are identical even though the actual coding sequences of homologous genes, or the number of copies of those genes, may not be. Homologous copies of a gene are termed **alleles**. In comparing alleles, it must be specified at what level of analysis the comparison is being made. When alleles are truly identical—in that their coding sequences and the number of copies are invariant—the individual is **homozygous** at that locus. At a coarser level, the alleles may be functionally identical despite subtle variations in nucleotide sequence—with the result either that the proteins produced from the two alleles are identical or that whatever differences there may be in amino acid sequence will have no bearing on the function of the protein. If the individual is being analyzed at the level of the protein phenotype, allelic homozygosity would again be an apt descriptor. However, if the analysis were at the level of the DNA—as occurs in restriction enzyme examination or nucleotide sequencing—then, despite functional identity, the alleles would be viewed as different and the individual would be **heterozygous** for that locus. Heterozygosity based on differences in the protein products of alleles has been detectable for decades and was the first hard evidence concerning the high degree of human biologic variability. In the past decade, analysis of DNA sequences has shown genetic variability to be much more common—differences in nucleotide sequence between individuals occur about once every 1200 nucleotides. Because of evolutionary selection against deleterious sequence changes, DNA variation in coding regions of genes occurs once every 2000 nucleotides, and less than half of those variants cause a change in an amino acid. However, the level of sequence variation among humans, regardless of their ethnic origins, is much less common (3- to 10-fold) than in our primate ancestors.

Mutation

Allelic heterozygosity most often results when different alleles are inherited from the egg and the sperm, but it also occurs as a consequence of spontaneous alteration in nucleotide sequence **(mutation)**. Genetic change occurring during formation of an egg or a sperm is called a **germinal mutation**. When the change occurs after conception—from the earliest stages of embryogenesis to dividing cells in the body of the oldest adult—it is termed a **somatic mutation**. As is discussed below, the role of somatic mutation in the etiology of human disease is now increasingly recognized.

The coarsest type of mutation is alteration in the number or physical structure of chromosomes. For example, **nondisjunction** (failure of chromosome pairs to separate) during **meiosis**—the reduction division that leads to production of mature ova and sperms—causes the embryo to have too many or too few chromosomes, a situation called **aneuploidy**. Rearrangement of chromosome arms, such as occurs in **translocation** or **inversion**, is a mutation even if breakage and reunion do not disrupt any coding sequence. Thus, the phenotypic effect of gross chromosomal mutations can range from profound (as in aneuploidy) to nil.

A bit less coarse, but still detectable cytologically, are **deletions** of part of a chromosome. Such mutations almost always alter phenotype, because a number of genes are lost; however, a deletion may involve only a single nucleotide, whereas about 1–2 million nucleotides (1–2 megabases) must be lost before the defect can be visualized by the most sensitive cytogenetic methods short of in situ hybridization. Molecular biologic techniques are needed to detect smaller losses.

Mutations of one or a few nucleotides in exons have several potential consequences. Changes in one nucleotide can alter which amino acid is encoded; if the amino acid is in a critical region of the protein, function might in this way be severely disturbed (eg, sickle cell disease). On the other hand, some amino acid substitutions have no detectable effect on function, and the phenotype is therefore unaltered by the mutation. Similarly, because the genetic code is **degenerate** (two or more different three-nucleotide sequences called **codons** encode the same amino acids), nucleotide substitution does not necessarily alter the amino acid sequence of the protein. Three specific codons signal termination of translation; thus, a nucleotide substitution in an exon that generates one of the stop codons usually causes a truncated protein, which is nearly always dysfunctional. Other nucleotide substitutions can disrupt the signals that direct splicing of the mRNA molecule and grossly alter the protein product. Finally, insertions and deletions of one or more nucleotides can have dramatic effects—any change that is not a multiple of three nucleotides disrupts the reading frame of the remainder of the exon—or potentially minimal effects (if the protein can tolerate the insertion or loss of an amino acid).

Mutations in introns may disrupt mRNA splicing signals or may be entirely silent with respect to the phenotype. A great deal of variation in nucleotide sequences among individuals (averaging one difference every few hundred nucleotides) resides within introns. Mutations in the DNA between adjacent genes may also be silent or may have a profound effect on phenotype if regulatory sequences are disrupted. A novel mechanism for mutation, which also helps explain clinical variation among relatives, has been discovered in myotonic dystrophy, Huntington disease, fragile X mental retardation syndrome, Friedreich ataxia, and other disorders. A region of repeated trinucleotide sequences close to or within a gene can be unstable in some families; expansion of the number of repeated units within this segment beyond a critical threshold is associated with a more severe phenotype, a phenomenon termed **anticipation**.

Mutations may occur spontaneously or may be induced by environmental factors such as radiation, medication, or viral infections. Both advanced maternal and paternal age favor mutation, but of different types. In women, meiosis is completed only when an egg ovulates, and chromosomal nondisjunction is increasingly common as the egg becomes older. The risk that an aneuploid egg will result increases exponentially and becomes a major clinical concern for women older than their early 30s. In men, mutations of a subtler sort—affecting nucleotide sequences—increase with age. Offspring of men over age 40 years are at an increased risk for having mendelian conditions, primarily autosomal dominant ones.

Genes in Individuals

For some quantitative traits such as adult height or serum glucose concentration in normal individuals, it is difficult to distinguish the contributions of individual genes; this is because in general, phenotypes are the products of multiple genes acting in concert. However, if one of the genes in the system is aberrant, a major departure from the "normal" or expected phenotype might arise. Whether the aberrant phenotype is serious (ie, a disease) or even recognized depends on the nature of the defective gene product and how resilient the system is to disruption. The latter point emphasizes the importance of homeostasis in both physiology and development—many mutations go unrecognized because the system can cope, even though tolerances for further perturbation might be narrowed.

In other words, most human characteristics and common diseases are **polygenic**, whereas many of the disordered phenotypes thought of as "genetic" are **monogenic** but still influenced by other loci in a person's genome.

Phenotypes due to alterations at a single gene are also characterized as **mendelian** , after Gregor Mendel, the monk and part-time biologist who studied the reproducibility and recurrence of variation in garden peas. He showed that some traits were **dominant** to other traits, which he called **recessive.** The dominant traits required only one copy of a "factor" to be expressed, regardless of what the other copy was, whereas the recessive traits required two copies before expression occurred. In modern terms, the mendelian factors are genes, and the alternative copies of the gene are alleles. Let *A* be the common (normal) allele and let *a* be a mutant allele at a locus: If the same phenotype is present whether the genotype is *A*/*a* or *a*/*a*, the phenotype is dominant, whereas if the phenotype is present only when the genotype is *a*/*a*, it is recessive.

In medicine, it is important to keep two considerations in mind: First, dominance and recessiveness are attributes of the phenotype, not the gene; and second, the concepts of dominance and recessiveness depend on how the phenotype is defined. To illustrate both points, consider sickle cell disease. This condition occurs when a person inherits two alleles for ^{S}-globin, in which the normal glutamate at position 6 of the protein has been replaced by valine; the genotype for the -globin locus is *HbS*/*HbS*, compared to the normal *HbA*/*HbA*. When the genotype is *HbS*/*HbA*, the individual does not have sickle cell disease, so this condition satisfies the criteria for being a recessive phenotype. But now consider the phenotype of sickled erythrocytes. Red cells with the genotype *HbS*/*HbS* clearly sickle—but, if the oxygen tension is reduced, so do cells with the genotype *HbS*/*HbA*. Therefore, sickling is a dominant trait.

A mendelian phenotype is characterized not only in terms of dominance and recessiveness but also according to whether the determining gene is on the X chromosome or on one of the 22 pairs of autosomes. Traits or diseases are therefore called autosomal dominant, autosomal recessive, X-linked recessive, and X-linked dominant.

Cook J et al. Mendelian inheritance. In: *Emery and*

Rimoin's Principles and Practice of Medical Genetics, 5th ed. Rimoin DL et al (editors). Churchill Livingstone, 2007.

Genes in Families

Since the first decade of the twentieth century, the patterns of recurrence of specific human phenotypes have been explained in terms of principles first described by Mendel in the garden pea plant. Mendel's second principle—usually referred to as his first[1]—is called the **law of segregation** and states that a pair of factors (alleles) that determines some trait separates (segregates) during formation of gametes. In simple terms, a heterozygous *(A/a)* person will produce two types of gametes with respect to this locus—one containing only *A* and one containing only *a*, in equal proportions. Offspring of this person will have a 50–50 chance of inheriting the *A* allele and a similar chance of inheriting the *a* allele.

[1] Mendel's first law stated that—from the perspective of the phenotype—it mattered not from which parent a particular mutant allele was inherited. For years this principle was thought to be too obvious to be codified as anybody's "law" and was therefore ignored. In fact, however, recent evidence from studies of human disorders suggests that certain genes are "processed" **(imprinted)** as they move through the gonad and that processing in the

testis is different from that in the ovary. Thus, not only is this first mendelian principle important, it was incorrect as originally formulated from observations in peas.

The concepts of genes in individuals and in families can be combined to specify how mendelian traits will be inherited.

Autosomal Dominant Inheritance

The characteristics of autosomal dominant inheritance in humans can be summarized as follows: (1) There is a vertical pattern in the pedigree, with multiple generations affected (Figure e2–3). (2) Heterozygotes for the mutant allele show an abnormal phenotype. (3) Males and females are affected with equal frequency and severity. (4) Only one parent must be affected for an offspring to be at risk for developing the phenotype. (5) When an affected person mates with an unaffected one, each offspring has a 50% chance of inheriting the affected phenotype. This is true regardless of the sex of the affected parent—specifically, male-to-male transmission occurs. (6) The frequency of sporadic cases is positively associated with the severity of the phenotype. More precisely, the greater the **reproductive fitness** of affected persons, the less likely it is that any given case resulted from a new mutation. (7) The average age of fathers is advanced for isolated (sporadic or new mutation) cases.

Figure e2–3

A pedigree illustrating autosomal dominant inheritance. Square symbols indicate males and circles females; open symbols indicate that the person is phenotypically unaffected, and filled symbols indicate that the phenotype is present to some extent.

Autosomal dominant phenotypes are often age-dependent, less severe than autosomal recessive ones, and associated with malformations or other physical features. They are **pleiotropic** in that multiple, even seemingly unrelated clinical manifestations derive from the same mutation, and **variable** in that expression of the same mutation among people will differ.

Penetrance is a concept associated with mendelian conditions—especially dominant ones—and the term is often misused. It should be defined as an expression of the frequency of appearance of a phenotype (dominant or recessive) when one or more mutant alleles are present. For individuals, penetrance is an all-or-none phenomenon—the phenotype is either present (penetrant) or not (nonpenetrant). The term **variability**—not "incomplete penetrance"—should be used to denote differences in expression of an allele.

The most frequent cause of apparent nonpenetrance is insensitivity of the methods for detecting the phenotype. If an apparently normal parent of a child with a dominant condition was in fact heterozygous for the mutation, the parent would have a 50% chance at each subsequent conception of having another affected child. A common cause of nonpenetrance in adult-onset mendelian diseases is death of the affected person before the phenotype becomes evident but after transmission of the mutant allele to offspring. Thus, accurate genetic counseling demands careful attention to the family medical history and high-resolution scrutiny of both parents of a child with a condition known to be a mendelian dominant trait.

When both alleles are expressed in the heterozygote, as in blood group AB, in sickle trait (HbS/HbA), in the major histocompatibility antigens (eg, A2B5/A3B17), or in sickle-C disease (HbS/HbC), the phenotype is called **codominant**.

In human dominant phenotypes, the mutant allele in homozygotes is almost always more severe than in heterozygotes.

Autosomal Recessive Inheritance

The characteristics of autosomal recessive inheritance in humans can be summarized as follows: (1) There is a horizontal pattern in the pedigree, with a single generation affected (Figure e2–4). (2) Males and females are affected with equal frequency and severity. (3) Inheritance is from both parents, each a heterozygote (carrier) and each usually clinically unaffected. (4) Each offspring of two carriers has a 25% chance of being affected, a 50% chance of being a carrier, and a 25% chance of inheriting neither mutant allele. Thus, two-thirds of all clinically unaffected offspring are carriers. (5) In matings between individuals, each with the same recessive phenotype, all offspring will be affected. (6) Affected individuals who mate with unaffected individuals who are not carriers have only unaffected offspring. (7) The rarer the recessive phenotype, the more likely it is that the parents are **consanguineous** (related).

Figure e2–4

A pedigree illustrating autosomal recessive inheritance. (Symbols as in Figure e2–3.)

Autosomal recessive phenotypes are often associated with deficient activity of enzymes and are thus termed **inborn errors of metabolism**. Such disorders include phenylketonuria, Tay-Sachs disease, and the various glycogen storage diseases and tend to be more severe, less variable, and less age-dependent than dominant conditions.

When an autosomal recessive condition is quite rare, the chance that the parents of affected offspring are consanguineous is increased. As a result, the prevalence of rare recessive conditions is high among inbred groups such as the Old Order Amish. On the other hand, when the autosomal recessive condition is common, the chance of consanguinity between parents of cases is no higher than in the general population (about 0.5%).

Two different *mutant* alleles at the same locus, as in HbS/HbC, form a **genetic compound** (compound heterozygote). The phenotype usually lies between those produced by either allele present in the homozygous state. Because of the large number of mutations possible in a given gene, many autosomal recessive phenotypes are probably due to genetic compounds. Sickle cell disease is an exception. Consanguinity is strong presumptive evidence for true homozygosity of mutant alleles and against a genetic compound.

X-Linked Inheritance

The general characteristics of X-linked inheritance in humans can be summarized as follows: (1) There is no male-to-male transmission of the phenotype (Figure e2–5). (2) Unaffected males do not transmit the phenotype. (3) All of the daughters of an affected male are heterozygous carriers. (4) Males are usually more severely affected than females. (5) Whether a heterozygous female is counted as affected—and whether the phenotype is called "recessive" or "dominant"—depends often on the sensitivity of the assay or examination. (6) Some mothers of affected males will not themselves be heterozygotes (ie, they will be homozygous normal) but will have a germinal mutation. The proportion of heterozygous (carrier) mothers is negatively associated with the severity of the condition. (7) Heterozygous women transmit the mutant gene to 50% of their sons, who are affected, and to 50% of their daughters, who are heterozygotes. (8) If an affected male mates with a heterozygous female, 50% of the male offspring will be affected, giving the false impression of male-to-male transmission. Of the female offspring of such matings, 50% will be affected as severely as the average hemizygous male; in small pedigrees, this pattern may simulate autosomal dominant inheritance.

Figure e2–5

A pedigree illustrating X-linked inheritance. (Symbols as in Figure e2–3.)

The characteristics of X-linked inheritance depend on phenotypic severity. For some disorders, affected males do not survive to reproduce. In such cases, about two-thirds of affected males have a carrier mother; in the remaining third, the disorder arises by new germinal mutation in an X chromosome of the mother. When the disorder is nearly always manifest in heterozygous females (X-linked dominant inheritance), females tend to be affected about twice as often as males; and on average an affected female transmits the phenotype to 50% of her sons and 50% of her daughters.

X-linked phenotypes are often clinically variable—particularly in heterozygous females—and suspected of being autosomal dominant with nonpenetrance. For example, Fabry disease (-galactosidase A deficiency) may be clinically silent in carrier women or may cause stroke, renal failure, or myocardial infarction by middle age.

Germinal mosaicism occurs in mothers of boys with X-linked conditions. The chance of such a mother having a second affected son or a heterozygous daughter depends on the fraction of her oocytes that carries the mutation. Currently, this fraction is impossible to determine. However, the presence of germinal mosaicism can be detected in some conditions (eg, Duchenne muscular dystrophy) in a family by analysis of DNA, and this knowledge becomes crucial for genetic counseling.

Mitochondrial Inheritance

Mutations in the genes encoded by the mitochondrial chromosome cause a variety of diseases that affect (in particular) organs highly dependent on oxidative metabolism, such as the retina, brain, kidneys, and heart. Because a person's mitochondria derive almost entirely from the ovum, the inheritance pattern is distinct from that of mendelian disorders and is termed "maternal" or, more appropriately, "mitochondrial." An affected woman can pass the defective mitochondrial chromosome to all of her offspring, whereas an affected man has little risk of passing his mutation to a child (Figure e2–6). Because each cell and the ovum contain many mitochondria and because each mitochondrion contains many chromosomes, two situations are possible: If every chromosome in every mitochondrion carries the same mutation, the person is said to be **homoplasmic** for the mutation. On the other hand, if only some of the mitochondrial chromosomes carry the mutation, the person is **heteroplasmic**. In the latter case, an offspring may inherit relatively few mitochondria bearing the mutation and have mild disease or no disease.

Figure e2–6

Mitochondrial ("maternal") inheritance. A mitochondrial genetic mutation, indicated by darkened symbols, is passed by the female (circle) to all of her offspring, including males (squares). Of subsequent offspring, males do not transmit the mutation, but females continue to transmit the mutation to all of their offspring because mitochondria are passed through ova, not sperm. For simplicity, although both parents are shown for the first generation, subsequent generations do not show the genetic partners, who are assumed to lack the mutation. Note: All or only some of the mitochondria may carry the mutation, a variable that affects the clinical expression of the mutation. (See text regarding homoplasmic and heteroplasmic individuals.)

Over 16,000 human genes have been identified or implied through their phenotypes and inheritance patterns in families. This total represents 60–70% of all genes thought to be encoded by the 22 autosomes, two sex chromosomes, and the mitochondrial chromosome. Victor McKusick and colleagues have coordinated an international effort to catalogue human mendelian variation.

Disorders of Multifactorial Causation

Many disorders cluster in families but are not associated with evident chromosomal aberrations or mendelian inheritance patterns. Examples include congenital malformations such as cleft lip, pyloric stenosis, and spina bifida; coronary artery disease; type 2 diabetes mellitus; and various forms of neoplasia. They are often characterized by varying frequencies in different racial or ethnic groups, disparity in sexual predilection, and greater frequency (but less than full concordance) in monozygotic than in dizygotic twins. This inheritance pattern is called "multifactorial" to signify that multiple genes interact with various environmental agents to produce the phenotype. The familial clustering is assumed to be due to sharing of both alleles and environment.

For most multifactorial conditions, there is little understanding of which particular genes are involved, how they and their products interact, and in what way different nongenetic factors contribute to the phenotype. For some disorders, biochemical and genetic studies have identified mendelian conditions within the coarse phenotype: Defects of the low-density lipoprotein receptor account for a small fraction of cases of ischemic heart disease (a larger fraction if only patients under age 50 years are considered); familial polyposis of the colon predisposes to adenocarcinoma; and some patients with emphysema have inherited deficiency of $_1$-proteinase ($_1$-antitrypsin) inhibitor. Despite these notable examples, this reductionistic preoccupation with mendelian phenotypes is unlikely to explain the great majority of human disease; but even so, in the last analysis, much of human pathology will prove to be associated with genetic factors in cause, pathogenesis, or both.

Our ignorance about fundamental genetic mechanisms in development and physiology has not completely restricted practical approaches to the genetics of multifactorial disorders. For example, recurrence risks are based on empirical data derived from observation of many families. The risk of recurrence of multifactorial disorders is increased in several instances: (1) in close relatives (siblings, offspring, and parents) of an affected individual; (2) when two or more members of a family have the same condition; (3) when the first case in a family is in the less commonly affected sex (eg, pyloric stenosis is five times more common in boys; an affected woman has a threefold to fourfold greater risk of having a child with pyloric stenosis); and (4) in ethnic groups in which there is a high incidence of a particular condition (eg, spina bifida is 40 times more common in whites—and even more frequent among the Irish—than in Asians).

For many apparently multifactorial disorders, too few families have been examined to have established empirical risk data. A useful approximation of recurrence risk in close relatives is the square root of the incidence. For example, many common congenital malformations have an incidence of 1:2500 to 1:400 live births; the calculated recurrence risks are thus in the 2–5% range—values that correspond closely to experience.

Chromosomal Aberrations

Any deviation from the structure and number of chromosomes as displayed in Figure e2–1 is, technically, a chromosomal aberration. Not all aberrations cause problems in the affected individual, but some that do not may lead to problems in offspring. About 1:200 live-born infants has a chromosomal aberration that is detected because of some effect on phenotype. This frequency increases markedly the earlier in fetal life the chromosomes are examined. By the end of the first trimester of gestation, most fetuses with abnormal numbers of chromosomes have been lost through spontaneous abortion. For example, Turner syndrome—due to the absence of one sex chromosome and the presence of a single X chromosome—is a relatively common condition, but it is estimated that only 2% of fetuses with this form of aneuploidy survive to term. Even more striking in live-born children is the complete absence of most autosomal trisomies and monosomies despite their frequent occurrence in young fetuses.

Types of Chromosomal Abnormalities

Major structural changes occur in either **balanced** or **unbalanced** form. In the latter, there is a gain or loss of genetic material; in the former, there is no change in the amount of genetic material but only a rearrangement of it. At the sites of breaks and new attachments of chromosome fragments, there may be permanent structural or functional damage to one gene or to only a few genes. Despite no visible loss of material, the aberration may nonetheless be recognized as unbalanced through an abnormal phenotype and the chromosomal defect confirmed by molecular analysis of the DNA.

Aneuploidy results from nondisjunction—the failure of a chromatid pair to separate in a dividing cell. Nondisjunction in either the first or second division of meiosis results in gametes with abnormal chromosomal constitutions. In aneuploidy, more or fewer than 46 chromosomes are present (Table e2–1). The following are all forms of aneuploidy: (1) **monosomy**, in which only one member of a pair of chromosomes is present; (2) **trisomy**, in which three chromosomes are present instead of two; and (3) **polysomy**, in which one chromosome is represented four or more times.

Table e2–1. Clinical phenotypes resulting from aneuploidy.

Condition	**Karyotype**	**Incidence at Birth**
Trisomy 13	47,XX or XY,+13	1:15,000
Trisomy 18	47,XX or XY,+18	1:11,000
Trisomy 21 (Down syndrome)	47,XX or XY,+21	1:900
Klinefelter syndrome	47,XXY	1:600 males
XYY syndrome	47,XYY	1:1000 males
Turner syndrome	45,X	1:2500 females
XXX syndrome	47,XXX	1:1200 females

If nondisjunction occurs in mitosis, **mosaic** patterns occur in somatic tissue, with some cells having one karyotype and other cells of the same organism another karyotype. Patients with a mosaic genetic constitution often have manifestations of each of the genetic syndromes associated with the various abnormal karyotypes.

Translocation results from an exchange of parts of two chromosomes.

Deletion is loss of chromosomal material.

Duplication is the presence of two or more copies of the same region of a given chromosome. The redundancy may occur in the same chromosome or in a nonhomologous chromosome. In the latter case, a translocation will also have occurred.

An **isochromosome** is a chromosome in which the arms on either side of the centromere have the same genetic material in the same order—ie, the chromosome has at some time divided in such a way that it has a double dose of one arm and absence of the other.

In an **inversion**, a chromosomal region becomes reoriented 180 degrees out of the ordinary phase. The same genetic material is present, but in a different order.

The Techniques of Medical Genetics

Hereditary disorders affect multiple organ systems and people of all ages. Many disorders are chronic ones, although acute crises often occur. The concerns of patients and families span a wide range of medical, psychological, social, and economic issues. These characteristics emphasize the need for pediatricians, internists, obstetricians, and family practitioners to provide medical genetics services for their patients. This section reviews the laboratory and consultative services available from clinical geneticists and the indications for their use.

Family History & Pedigree Analysis

The first step in considering how important genetic factors might be in the clinical situation of a patient is obtaining a detailed family history. At a minimum, a patient should be queried in detail about all first-degree relatives—parents, siblings, and offspring—(age, sex, health status if alive, including major illnesses; cause of death) and more distant relatives with reference to the particular condition at issue. Ethnicity of both sides of the family should be noted; any disorders known to be especially prevalent in a particular ethnic group should be asked about specifically. Once the family history is obtained, it should be analyzed; medical geneticists and genetic counselors are trained in this task and are particularly valuable when the busy clinician has neither the time nor the staff to pursue the information. A pedigree diagram (eg, Figure e2–3) with the symbols filled in to indicate the presence of a condition can be instructive in suggesting a mode of inheritance. Once targeted genetic testing of the **proband** produces a result, the diagram also proves useful in identifying relatives who might benefit from counseling about similar testing.

Cytogenetics

Cytogenetics is the study of chromosomes by light microscopy. The chromosomal constitution of a single cell or an entire individual is specified by a standardized notation. The total chromosome count is determined first, followed by the sex chromosome complement and then by any abnormalities. The autosomes are all designated by numbers from 1 to 22. A plus (+) or minus (–) sign indicates, respectively, a gain or loss of chromosomal material. For example, a normal male is 46,XY, whereas a girl with Down syndrome caused by trisomy 21 is 47,XX,+21; a boy with Down syndrome caused by translocation of chromosome 21 to chromosome 14 in a sperm or an egg is 46,XY,–14,+t(14;21).

Chromosomal analyses are done by growing human cells in tissue culture, chemically inhibiting mitosis, and then staining, observing, photographing, sorting, and counting the chromosomes. The display of all of the chromosomes is termed the **karyotype** (Figure e2–1) and is the end result of the technical aspect of cytogenetics.

Specimens for cytogenetic analysis can be obtained for routine analysis from the peripheral blood, in which case T lymphocytes are examined; from amniotic fluid for culture of amniocytes; from trophoblastic cells from the chorionic villus; from bone marrow; and from cultured fibroblasts, usually obtained from a skin biopsy. Enough cells must be examined so that the chance of missing a cytogenetically distinct cell line (a situation of mosaicism) is statistically low. For most clinical indications, 20 mitoses are examined and counted under direct microscopic visualization, and two are photographed and karyotypes prepared. Observation of aberrations usually prompts more extended scrutiny and in many cases further analysis of the original culture.

A variety of methods can be used to reveal banding patterns—unique to each pair of chromosomes—in the analysis of aberrations. The number of bands that can be visualized is a function of how "extended" the chromosomes are, which in turn depends primarily on how early in metaphase (or even in prophase for the most extensive banding) mitosis was arrested. The "standard" karyotype reveals about 400 bands per haploid set of chromosomes, whereas a prophase karyotype might reveal four times that number. As invaluable as extended karyotypes are in certain clinical circumstances, their interpretation is often difficult—in terms of the time and effort required and of ambiguity about what is abnormal, what is a normal variation, and what is a technical artifact. In situ hybridization with DNA probes for specific chromosomes or regions of chromosomes can be labeled and used to identify subtle aberrations. Given proper technique, fluorescent in situ hybridization (FISH) yields sensitivities and specificities of almost 100%. Some applications are being used routinely and marketed commercially, though the Food and Drug Administration (FDA) has only recently begun to approve probes for clinical use.

The tips of chromosomes are called **telomers**. An area of particular relevance is the use of FISH to detect heretofore undetectable deletions in the regions of chromosomes just proximal to their tips (subtelomeric). Comparative genomic hybridization (CGH) provides a method, using DNA chip-based technology, to survey a patient's genome for many more cytogenetically undetectable deletions than current FISH approaches. The chips in current commercial use contain 400–600 probes that include all sites of deletions and insertions of known clinical importance as well as regions of uncertain significance. Systems capable of scanning many thousands of regions of the human genome are being introduced.

Indications for Cytogenetic Analysis

The current indications are listed in Table e2–2. A wide array of clinical syndromes has been found to be associated with chromosomal aberrations, and analysis of the karyotype is useful any time a patient is discovered to have the manifestations of one of these syndromes. When a chromosomal aberration is revealed, not only does the patient's physician obtain valuable information about prognosis, but the parents gain insight into the cause of their child's problems and the family can be counseled accurately—and usually reassured—about the risks of recurrence.

Table e2–2. Indications for cytogenetic analysis.
Patients of any age who are grossly retarded physically or mentally, especially if there are associated anomalies.
Any patient with ambiguous internal or external genitalia or suspected hermaphroditism.
Girls with primary amenorrhea and boys with delayed pubertal development. Up to 25% of patients with primary amenorrhea have a chromosomal abnormality.
Males with learning or behavioral disorders who are taller than expected (based on parental height).
Certain malignant and premalignant diseases (see Tables e2–7 and e2–8).

Parents of a patient with chromosome translocation.
Parents of a patient with a suspected chromosomal syndrome if there is a family history of similarly affected children.
Couples with a history of multiple spontaneous abortions of unknown cause.
Couples who are infertile after more common obstetric and urologic causes have been excluded.
Prenatal diagnosis (see Table e2–6).

Mental retardation is a frequent component of congenital malformation syndromes. Any person with unexplained mental retardation should be studied by chromosomal analysis.

Recent studies using fluorescent probes for subtelomeric genetic sequences have shown subtle rearrangements or deletions in about 6% of patients who have otherwise unexplained mental retardation with or without dysmorphic features. These deletions occur either because of de novo mutation or because of rearrangements due to balanced parental translocations. These chromosomal aberrations are generally too small to be detected by routine cytogenetic analysis. Abnormalities of sexual differentiation can be understood only after the patient's **genetic sex** is clarified. Hormonal therapy and plastic surgery can to some extent determine **phenotypic sex**, but genetic sex is dictated by the complement of sex chromosomes. The best-known example of dichotomy between the genetic sex and phenotypic sex is the **testicular feminization syndrome**, in which the chromosomal constitution is 46,XY but, because of a defect in the testosterone receptor protein (specified by a gene on the Y chromosome), the external phenotype is completely female.

Failure or delay in developing secondary sexual characteristics occurs in **Turner syndrome** (the most common cause being a form of aneuploidy, ie, monosomy for the X chromosome, 45,X), in **Klinefelter syndrome** (the most common karyotype is 47,XXY), and in other much rarer chromosomal aberrations.

Tall stature is perhaps the only consistent phenotypic feature associated with having an **extra Y chromosome** (karyotype 47,XYY); most men with this chromosomal aberration lead normal lives, and thus tall stature in a male is itself no indication for chromosomal analysis. However, some evidence suggests that an increased prevalence of learning difficulties may be associated with this aberration. Furthermore, Klinefelter syndrome often causes tall stature, albeit with a eunuchoid habitus, and learning and behavioral problems. Thus, the combination of learning or behavioral difficulties and unexpectedly increased height in a male should prompt consideration of cytogenetic analysis.

As discussed below, most tumors are associated with chromosomal aberrations, some of which are highly specific for certain malignancies. Cytogenetic analysis of tumor tissue may assist in diagnosis, prognosis, and management.

Whenever a person is shown to have a chromosome translocation—whether it is balanced and asymptomatic or unbalanced, causing a syndrome—the physician should consider the importance of identifying the source of the translocation. If the proband is a child and the parents are interested in having more children, both parents should be studied cytogenetically. How far the primary physician or consultant should go in tracking a translocation through a family is an unsettled question with legal and ethical as well as medical implications. Certainly the proband (if an adult) or the parents of the proband need to be counseled and the potential risks to relatives discussed. The physician should document, both in the medical record and by correspondence, that the burden of disclosing relevant data to the extended family has been assumed by specific named individuals.

Inability to produce offspring, either through failure to conceive or as a result of repeated miscarriages, is a frustrating and discouraging problem for affected couples and their physicians. Considerable progress in the urologic and gynecologic understanding of infertility has benefited many couples. However, chromosomal aberrations remain an important problem in reproductive medicine, and cytogenetic analysis should be utilized at some stage in extended evaluations. Infertility is common in both Klinefelter and Turner syndromes, either of which may be associated with mild external signs—particularly if the chromosomal aberration is mosaic. Any early spontaneous abortion may be due to fetal aneuploidy. Recurrence may be due to parental translocation predisposing to an unbalanced fetal karyotype.

Biochemical Genetics

Biochemical genetics deals not only with enzymatic defects but also with proteins of all functions, including cytoskeletal and extracellular structure, regulation, and receptors. The principal functions of the biochemical genetics laboratory are to determine the presence or absence of proteins, to assess the qualitative characteristics of proteins, and to verify the effectiveness of proteins in vitro. The key elements from the referring clinician's perspective are: (1) to indicate what the suspected clinical diagnoses are, and (2) to make certain that the proper specimen is obtained and transported to the laboratory in a timely manner.

Indications for Biochemical Investigations

Some inborn errors are relatively common in the general population, eg, hemochromatosis, defects of the low-density lipoprotein receptor, and cystic fibrosis (Table e2–3). Others, although rare across the entire population, are common in certain ethnic groups, such as Tay-Sachs disease in Ashkenazic Jews, sickle cell disease in African Americans, and thalassemias in populations from around the Mediterranean basin and Asia. Many of these disorders are autosomal recessive, and the frequency of heterozygotes is many times that of the fully expressed disease. Screening for carrier status can be effective if certain requirements are satisfied (Table e2–4). For example, all of the United States and the District of Columbia require screening of newborns for phenylketonuria and often other metabolic diseases. Such programs are cost-effective even for rare conditions such as phenylketonuria, which occurs in only one of every 11,000 births. Unfortunately, not all disorders that meet the requirements in Table e2–4 are screened for in every state. Furthermore, compliance is highly variable among programs, and follow-up diagnostic tests, management, and counseling are in some cases inadequate. Babies most likely to be missed are those born at home and those discharged before they have digested much milk or formula. In some states, parents can refuse to have their infants studied. Several commercial laboratories have marketed screening for over 35 inborn errors of metabolism to hospitals. This **supplemental newborn screening** involves tandem mass spectroscopic analysis of the same blood spots used in state-mandated programs.

Table e2–3. Representative inborn errors of metabolism.

General Class of Defect	**Example**	**Biochemical Defect**	**Inheritance**
Aminoacidopathy	Phenylketonuria	Phenylalanine	AR

		hydroxylase	
Connective tissue	Osteogenesis imperfecta type II	$_1$(I) and $_2$(I) procollagen	AD
Gangliosidosis	Tay-Sachs disease	Hexosaminidase A	AR
Glycogen storage disease	Type I	Glucose-6-phosphatase	AR
Immune function	Chronic granulomatous disease	Cytochrome *b*, -chain	XL
Lipid metabolism	Familial hypercholesterolemia	Low-density lipoprotein receptor	AD
Mucopolysaccharidosis (MPS)	MPS II (Hunter syndrome)	Iduronate sulfatase	XL
Porphyria	Acute intermittent	Porphobilinogen deaminase	AD
Transport	Cystic fibrosis (CF)	CF transmembrane conductance	AR

		regulator	
Urea cycle	Citrullinemia	Arginosuccinate synthetase	AR

AR, autosomal recessive; AD, autosomal dominant; XL, X-linked recessive.

Table e2–4. Requirements for effective population screening for inborn errors of metabolism.
1. The disease should be clinically severe or have potentially severe consequences.
2. The natural history of the disease should be understood.
3. Effective treatment should be generally available and depend on early diagnosis for optimal results.
4. The disease incidence should be high enough to warrant screening.
5. The screening test should have favorable specificity (low false-positive rate) and sensitivity (low false-negative rate).
6. The screening test should be available for and used by the entire population at risk.
7. An adequate system for follow-up of positive results

should be provided.
8. The economic cost-benefit analysis should favor screening and treatment.

Use of the biochemical genetics laboratory for other than screening purposes must be justified by the need for data on which to base a diagnosis of specific disorders or classes of related disorders. The possibilities are limited only by the extent of knowledge, the enthusiasm of the primary clinician or consultant, the willingness of the patient or family to pursue the diagnosis and specimens to be taken, and the availability of a laboratory to examine the specimens.

Though many inborn defects are so subtle they escape detection, there are a number of clinical situations in which an inborn error should be part of the differential diagnosis. The urgency with which the investigation is undertaken will vary depending on the severity of the disorder and the availability of treatment. Table e2–5 lists various clinical presentations.

Table e2–5. Manner of presentation of inborn errors of metabolism.

Presentation and Course	**Examples**

Acute metabolic disease of the neonate	Galactosemia, urea cycle disorders
Chronic disorders with little progression after infancy	Phenylketonuria, hypothyroidism
Chronic disorders with insidious, incessant progression	Tay-Sachs disease
Disorders causing abnormalities of structure	Skeletal dysplasias, Marfan's syndrome
Disorders of transport	Cystinuria, lactase deficiency
Disorders that determine susceptibilities	Low-density lipoprotein receptor deficiency, agammaglobulinemia
Episodic disorders	Most porphyrias, glucose-6-phosphate deficiency
Disorders causing anemia	Pyruvate kinase deficiency, hereditary spherocytosis
Disorders interfering with hemostasis	Hemophilia A and B, von Willebrand disease
Congenital disorders with no possibility of reversal	Testicular feminization
Disorders with	Pseudohypoparathyroidism,

protean manifestations	hereditary amyloidoses
Inborn errors with no clinical effects	Pentosuria, histidinemia

The possibility of acute metabolic disease of the neonate is the most important indication, because prompt diagnosis and treatment may often make the difference between life and death. The clinical features are nonspecific because the newborn has a limited repertoire of responses to severe metabolic insults. The physician must be both inclusive and systematic in evaluating such ill babies.

DNA Analysis

Direct inspection of nucleic acids—often called "molecular genetics" or "DNA diagnosis"—is achieving an increasingly prominent role in a number of clinical areas, including oncology, infectious disease, forensics, and the general study of pathophysiology. A major impact has been in the diagnosis of mendelian disorders. Molecular testing is available for more than 1000 separate hereditary conditions. Once a particular gene is shown to be defective in a given condition, the nature of the mutation itself can be determined, often by sequencing the nucleotides and comparing the array with that of a normal allele. One of a variety of techniques can then be used to determine whether that same mutation is present in other patients with the same disorder. Genetic heterogeneity is so extensive that most mendelian conditions are associated with numerous mutations at one locus—or occasionally multiple loci—that produce the same phenotype. Mutations at no less than 35 different genes cause nonsyndromic retinitis pigmentosa, and changes in at least 12 genes cause familial hypertrophic cardiomyopathy. This fact complicates DNA diagnosis of patients and screening for carriers of defects in specific genes.

A few conditions are associated with relatively few mutations or with only one highly prevalent mutation. For example, all sickle cell disease is caused by exactly the same change of glutamate to valine at position 6 of -globin, and that substitution in turn is due to a change of one nucleotide at the sixth codon in the -globin gene. But such uniformity is the exception. In cystic fibrosis, about 70% of white heterozygotes have an identical deletion of three nucleotides that causes loss of a phenylalanine residue from a chloride transport protein; however, the remaining 30% of mutations of that protein are diverse (over 1500 have been discovered), so that no simple screening test will detect *all* carriers of cystic fibrosis.

Reviews of the current technical status of DNA analysis appear regularly in the medical literature. Polymerase chain reaction (PCR) studies have revolutionized many aspects of molecular biology, and DNA diagnosis has come to involve this technique in many instances. If the sequences of the 10–20 nucleotides at the ends of a region of DNA of interest (such as a portion of a gene) are known, then "primers" complementary to these sequences can be synthesized. When even a minute amount of DNA from a patient (eg, from a few leukocytes, buccal mucosal cells, or hair bulbs) is combined with the primers in a reaction mixture that replicates DNA—and after several dozen cycles are then performed—the region of DNA between the primers will be amplified exponentially. For example, the presence of early HIV infection can be detected after PCR amplification of a portion of the viral genome. A variety of new techniques are being studied in an attempt to permit analysis of many potential genetic variations in one individual in a very short time. For example, "DNA chip arrays," about the size of a microscope cover slip, can contain tens of thousands of specific nucleotide sequences. When an individual's DNA is denatured and allowed to hybridize to the array, pairing of sequences causes a fluorescent signal that can be detected by a laser microscope and recorded and interpreted by a computer.

Indications for DNA Diagnosis

The basic requirement for the use of nucleic acids in the diagnosis of hereditary conditions is that a **probe** be available for the gene in question. The probe may be a piece of the actual gene, a sequence close to the gene, or just a few nucleotides at the actual mutation. The closer the probe is to the actual mutation, the more accurate and the more useful will be the information derived. DNA diagnosis involves one of two general approaches: (1) direct detection of the mutation or (2) linkage analysis, whereby the presence of a mutation is inferred from the nature of a probe DNA sequence remote from the mutation. In the latter approach, as the probe moves farther from the mutation, the chances increase that recombination will have separated the two sequences and confused the interpretation of the data.

DNA diagnosis is finding frequent application in presymptomatic detection of individuals with age-dependent disorders such as Huntington disease and adult polycystic kidney disease, screening for carriers of autosomal recessive conditions such as cystic fibrosis and thalassemias, screening for female heterozygotes of X-linked conditions such as Duchenne muscular dystrophy and hemophilia A and B, and prenatal diagnosis (see below). For some conditions in which serious complications occur in adolescence or early adulthood—such as von Hippel–Lindau syndrome, hereditary hemorrhagic telangiectasia, and familial polyposis coli—genetic testing at an early age can identify those relatives who need frequent clinical monitoring and prophylactic management; almost as important, relatives who test negative for the mutation can be spared the inconvenience, cost, and risk of clinical tests. In all instances of DNA testing, primary care providers and specialists alike must be mindful that substantive ethical, psychological, legal, and social issues remain unresolved. For example, some conditions for which hereditary susceptibility can be readily defined (such as Alzheimer disease, Huntington disease, and many cancers) have no effective therapy at this time. For these same conditions, health insurance and life insurance providers may be especially interested in learning who among their current or prospective customers is at higher risk. Many states have enacted legislation to protect people identified as having a heightened genetic risk of disease. In 2008, the federal Genetic Information Nondiscrimination Act (GINA) was signed into law. Its prohibitions against unfair discrimination in health insurance and employment take effect in 2009. The protections are limited to those individuals who are detected as having a genetic susceptibility to a disease that is not evident clinically.

Logistics of DNA Diagnosis

Lymphocytes are a ready source of DNA; 10 mL of whole blood yields up to 0.5 mg of DNA, enough for dozens of analyses based on hybridization, each of which requires only 5 mcg. If the analysis is quite narrowly focused on a specific mutation (such as in a family study, in which only one specific nucleotide change is addressed), PCR analysis can often be used and the amount of DNA needed is truly infinitesimal—a few hair bulbs or sperm are adequate. Once isolated, the DNA sample can be divided into aliquots and frozen. Alternatively, lymphocytes can be transformed with viruses into lymphoblasts; these cells are immortal, can be frozen, and—whenever DNA is required—can be thawed, propagated, and their DNA isolated. These stored specimens provide access to a person's genome long after the individual dies. This is such an important advantage that many clinical genetics centers and commercial laboratories "bank" DNA from patients and informative relatives even if the samples cannot be put to use immediately. The specimens may later prove invaluable to relatives or to other patients being evaluated. DNA in some instances has become more reliable than the medical records.

Blood for DNA isolation should be drawn in ethylenediaminetetraacetic acid (EDTA) anticoagulant (lavender-top tubes); blood for lymphoblast culture should be drawn in heparin (green-top tubes). Neither should be frozen. Specimens for DNA isolation can be stored or shipped at room temperature over a period of a few days. Lymphoblast cultures should be established within 48 hours, so prompt shipment is essential. For one or a few specific DNA analyses, some laboratories accept a swab that has been placed between the cheek and gum for a minute (buccal swab); enough cells adhere to the fibers that DNA from the subject can be isolated.

Fetal DNA can be isolated from amniotic cells, from trophoblastic cells taken by chorionic villus sampling, or from either cell type grown in culture. Samples need to be processed promptly but can be shipped by overnight mail and must not be frozen.

Prenatal Diagnosis

It is possible to diagnose in utero, before the middle of the second trimester, several hundred mendelian disorders, all chromosome aberrations, and a number of congenital malformations that are not mendelian. The first step toward prenatal diagnosis is taken when the expecting couple, the primary care provider, or the obstetrician thinks of the need for it. Recent surveys suggest that even for the most common indication for such service—advanced maternal age—less than 50% of all women 35 years and older in the United States are offered prenatal testing.

Techniques Used in Prenatal Diagnosis

Prenatal diagnosis depends on the ability to assay the fetus directly (fetal blood sampling, fetoscopy), indirectly (analysis of amniotic fluid, amniocytes or trophoblastic cells, ultrasound), or remotely (analysis of maternal serum). Some of these techniques satisfy the requirements for screening (Table e2–4) and should be offered to all pregnant women; others carry considerable risk and should be reserved for specific circumstances. A few centers are developing preimplantation diagnosis of the embryo; a single cell is plucked from the six- to eight-cell blastocyst, which has been cultured after in vitro fertilization, generally without harming future development. The chromosomes of the cell can be studied by FISH or the genes by PCR. Another new approach, with considerable potential, is isolation of fetal cells that are circulating in minute numbers in the maternal circulation.

Ultrasound scanning of the fetus is a safe, noninvasive procedure that can diagnose gross skeletal malformations as well as nonbony malformations known to be associated with specific diseases, eg, measurement of nuchal translucency in Down syndrome (see below). Some obstetricians routinely perform fetal ultrasound at least once between 12 and 20 weeks of gestation.

Other prenatal diagnostic procedures—fetoscopy, fetography, and amniography—are more invasive and a definite risk to the mother and fetus. They are indicated only if the risk of the suspected abnormality is high and the information cannot be obtained by other means.

Maternal serum can be assayed for multiple markers that predict the risk that the fetus has a neural tube defect (elevated -fetoprotein) or one of the common autosomal trisomies. Such screening is offered in the first trimester so that the results can be used, along with ultrasound and maternal age, to counsel the couple about the utility of further testing, such as chorionic villus sampling or amniocentesis.

All of the cytogenetic, biochemical, and DNA analytic techniques discussed above can be applied to specimens from the fetus. Aside from screening for -fetoprotein in maternal serum to detect neural tube defects, analysis of fetal chromosomes is the most frequently performed test. Chromosomal analysis can be performed on amniotic cells and on trophoblastic cells grown in culture and directly on any trophoblastic cells that happen to be undergoing mitosis. Amniotic fluid cells are derived primarily from the fetal urinary system. Amniocentesis can be performed during gestational weeks 16–18 to permit unhurried sample analysis, transmission of results, and reproductive decisions. The time from obtaining the sample to a final reading of the karyotype has now been shortened to a week or so, and automated methods may reduce the time a bit further. Chorionic villus sampling (CVS) for trophoblastic cells (derived embryologically from the same fertilized egg as the fetus) is usually done during gestational weeks 10–13. If the tissue can be analyzed directly, cytogenetic results can be obtained within a few hours; however, the quality of the karyotypes is inferior to that from cultured cells, and most laboratories routinely culture cells and reexamine any suspected abnormalities. The advantage of CVS is that the results are available early in pregnancy, so that termination, if elected, can occur earlier in the pregnancy and the obstetric complications of termination are fewer.

The risk of CVS is somewhat higher than that of amniocentesis, though both are relatively safe. Between 0.5% and 1% of pregnancies are lost as a complication of CVS, whereas less than one in 300 amniocenteses result in fetal loss. Some centers offer "early amniocentesis," performed during gestational weeks 12–14; the magnitude of the risks is similar to that of CVS. These figures are lower than—but are in addition to—the 2–3% spontaneous abortion rate after the first trimester ends.

Indications for Prenatal Diagnosis

The indications for prenatal diagnosis are listed in Table e2–6. A few deserve comment.

Table e2–6. Indications for prenatal diagnosis.

Indications	**Methods**
Advanced maternal age, one parent a carrier of a translocation, previous child with chromosome aberration, intrauterine growth delay	Cytogenetics (amniocentesis, chorionic villus sampling)
Biochemical disorder	Protein assay, DNA diagnosis
Congenital anomaly	Ultrasound, fetal cytogenetics
Screening for neural tube defects and trisomy	Maternal multiple marker screening, ultrasound

Most studies done for advanced maternal age will detect no chromosomal aberration, and the couple will be reassured by this news. However, it is always appropriate to emphasize that the average risk of producing a child with a defect evident at birth, such as a physical malformation or some inborn error of metabolism, is about 3%, and that the risk increases with the age of either parent. Simply examining the chromosomes reduces this risk minimally. On the other hand, unless one of the other indications is present, it is simply not possible to "screen" a pregnancy for most birth defects (neural tube defects being an exception).

Individuals contemplating pregnancy—especially those of Ashkenazic Jewish or other white ethnicity—should be offered screening for the most common mutations in the *CFTR* gene that cause cystic fibrosis. If both partners are detected as being carriers, prenatal diagnosis of a fetus would be an option for them.

A history for cytogenetic aberrations emphasizes a chromosomal defect in a parent, a family history of a chromosomal defect, or a previous child or conceptus with a defined or undefined chromosomal defect. The factors that render some couples susceptible to repeated episodes of aneuploidy are unclear, and routine prenatal testing is warranted once a defect has occurred.

Cytogenetic analysis of the fetus will of course provide information about the sex chromosomes. Some couples do not desire advance knowledge of the sex of their child, and the person transmitting the results to the couple should always address this issue first. On the other hand, some couples *only* want to know the sex of the fetus and plan to terminate the pregnancy if the undesired sex is detected. Few centers in the United States consider sex selection to be an appropriate indication for prenatal diagnosis.

The level of -fetoprotein in maternal serum changes with gestational age, with the mother's medical status, and with abnormalities of the fetus. If the first two factors can be well controlled, the assay can be used to provide information about the fetus. Levels are expressed as multiples of the median value for a particular gestational age. Higher than normal levels are associated with open neural tube defects (the conditions for which the test was developed), recent or impending fetal demise, gastroschisis, and fetal renal disease. Extremely high levels are highly specific for fetal anomalies—a level three times the median increases 20-fold the risk of meningomyelocele or anencephaly. Low -fetoprotein levels in maternal serum are associated with fetal trisomy, especially Down syndrome; the reason for this association remains unclear. The addition of two other analytes in maternal serum—human chorionic gonadotropin (hCG) and unconjugated estriol (uE3)—to the assay for -fetoprotein (to produce the "triple screen") enhances by several times the ability to detect a fetus with trisomy 21 and trisomy 18. Measuring in the first trimester both serum pregnancy-associated plasma protein A and the translucency of the fetal neck by ultrasound—followed by routine triple screening in the second trimester—improves the rate of detection of Down syndrome to about 85% while reducing false-positive results to about 1%. A positive result on any of these screening protocols for trisomy should be followed by offering the woman amniocentesis to confirm the diagnosis.

Neoplasia: Chromosomal & DNA Analysis

Studies of both chromosomes and nucleic acids support Boveri's 1914 hypothesis that cancer is caused by a change in genetic material at the cellular level. Two classes of genes have been discovered that function in neoplastic transformation.

Oncogenes arise from preexisting normal genes (protooncogenes) that have been altered by both viral and nonviral factors. As a result, the cells synthesize either normal proteins in inappropriate amounts or proteins that are aberrant in structure and function. Many of these proteins are cellular growth factors or receptors for growth factors. The net result of oncogene activation is unregulated cell division. Mutations that activate oncogenes almost always arise in somatic cells and are not usually inherited. Although some oncogenes are more likely to be activated in certain tumors, in general the same mutations may be found in neoplasia arising in different cells and tissues.

Tumor suppressor genes can be viewed as the antithesis of oncogenes. Their normal function is to suppress transformation; mutation in both alleles is necessary to obliterate this important function. The first mutant allele at any tumor suppressor gene might arise spontaneously or might be inherited; mutation in the other allele (the "second hit") almost always arises spontaneously, but by any of a number of molecular mechanisms. These genes show considerably more tumor specificity than do oncogenes; however, although some specific mutations are necessary for certain tumors to arise, no loss of single tumor suppressor function is sufficient. Clearly, a person who inherits one copy of a mutant tumor suppressor gene is at increased risk that in some susceptible cell, at some time during life, the function of that gene will be lost. This susceptibility is inherited as an autosomal dominant trait. For example, mutation in one allele of the *p53* locus results in the Li-Fraumeni syndrome (151623), in which susceptibility before age 45 years to sarcomas and other tumors occurs in males and females in successive generations. Inherited mutations in this locus also increase the risk that a second tumor will develop following radiation or chemotherapy for the first tumor, suggesting that the initial treatment may induce a "second hit" in a *p53* locus in another tissue. However, inheriting a *p53* mutation is not a guarantee that cancer will develop at an early age; much more needs to be learned about the pathogenesis of neoplasia before the genetic counseling of families with a molecular predisposition to cancer is clarified. *BRCA1,* a gene that predisposes women to breast (114480) and ovarian cancer, is another example of a tumor suppressor gene. Women who inherit one mutant allele of *BRCA1* have, on average, a 60–80% lifetime risk of developing breast cancer, and the average age of tumor detection is in the fifth decade. Their risk of developing ovarian cancer is 34–45%. For both females and males with certain mutations in *BRCA1,* the risks of colon and pancreatic cancer are increased severalfold over that of the general population.

In selected cases, a patient's DNA can be analyzed for the presence of a mutated gene and thereby that individual's risk for developing a tumor can be assessed. Examples are retinoblastoma (189200), certain forms of Wilms tumor (194070), breast cancer (114489), and familial colon cancer (114500). To illustrate how noninvasive and sensitive the methodology has become, it is possible to analyze stool for the presence of mutations in tumor suppressor genes that might indicate the presence of a clinically undetected adenocarcinoma of the colon. The analysis—not yet in general use—depends on the ability of the PCR to amplify minute quantities of the mutant DNA present in epithelial cells shed from the tumor.

A third class of genes that predispose to malignancy has been discovered in the past few years. So-called **mutator genes** have joined oncogenes and tumor suppressor genes as risk factors. Mutator genes normally function to repair damage to DNA that occurs from environmental insults such as exposure to carcinogens and ultraviolet irradiation. When a mutator gene is mutated itself, DNA damage accumulates and eventually affects oncogenes and tumor suppressor genes, thereby making cancer more likely. Hereditary nonpolyposis colon cancer (HNPCC) is one familial syndrome due to mutations in one or another of the five mutator genes identified thus far (*MSH2* and *MLH1* being the most commonly responsible for HNPCC).

This exciting work on the molecular nature of oncogenesis was preceded by years of study of the cytogenetics of tumors. Indeed, the retinoblastoma tumor suppressor gene was ultimately isolated because a small number of patients with this tumor have a constitutive deletion of chromosome 13 where this gene maps. Other chromosomal aberrations have been found to be highly characteristic of—or even specific for—certain tumors (Table e2–7). Detection of one of these cytogenetic aberrations can thus aid in diagnosis.

Table e2–7. Chromosome aberrations associated with representative solid tumors.

Tumor	**Chromosome Aberration**
Meningioma	del(22)(q11)[1]
Neuroblastoma	del(1)(p36), del(11)(q23)
Renal cell carcinoma	del(3)(p14.2–p25) or translocation of this region
Retinoblastoma, osteosarcoma	del(13)(q14.1) or translocation of this region
Small-cell lung carcinoma	del(3)(p14–p23)
Wilms' tumor	del(11)(p15)

[1] Nomenclature means, "a deletion at band q11 of chromosome 22."

Hematologic malignancies are especially amenable to study because of the relative ease of performing cytogenetic analysis. Such malignancies are associated with over 100 specific chromosomal rearrangements, primarily translocations. Most of these rearrangements are restricted to a specific type of cancer (Table e2–8), and the remainder occur with many cancers.

Table e2–8. Chromosomal aberrations associated with representative hematologic malignancies.

Tumor	**Chromosomal Aberration**
Leukemia	
Acute myeloblastic	t(8;21)(q22;q11)[1]
Acute promyelocytic	t(15;17)(q22;q11–q12)
Acute monocytic	t(10;11)(p15–p11;q23)
Chronic myelogenous	t(9;22)(q34;q11)
Lymphomas	
Burkitt	t(8;14)(q24.1;q32.3)
B cell	t(1;14)(q42;q43)
T cell	inv, del, and t of 1p13–p12
Premalignancy	
Polycythemia vera	del(20)(q11)

[1] Nomenclature means, "a translocation with the union at band q22 of chromosome 8 and q11 of chromosome 21."

In the leukemias, the chromosomal aberration is the basis of one of the subclassifications of the disease. When cytogenetic information is combined with the histologic classification, it is possible to define subsets of patients in whom response to therapy, clinical course, and prognosis are predictable. If at the time of diagnosis there are no chromosomal changes in the bone marrow cells, the survival time is longer than if any or all of the bone marrow cells have abnormal cytogenetic characteristics. As secondary chromosomal changes occur, the leukemia becomes more aggressive, often associated with drug resistance and a reduced chance for complete or prolonged remission. The least ominous chromosomal change is numerical alteration without morphologic abnormality.

Less cytogenetic information is available for lymphomas and premalignant hematologic disorders than for leukemia. In Hodgkin disease, studies have been limited by the low yield of dividing cells and the low number of clear-cut aneuploid clones, so that complete chromosomal analyses with banding are available for far fewer patients with Hodgkin disease than for any other type of lymphoma. In Hodgkin disease, the modal chromosomal number tends to be triploid or tetraploid. About one-third of the samples have a 14q+ chromosome. In non-Hodgkin lymphomas, high-resolution techniques of banding detect abnormalities in 95% of cases. Cytogenetic findings are now being correlated with the immunologic and histologic features and with prognosis.

In Burkitt lymphoma, a solid tumor of B cell origin, 90% of patients have a translocation between the long arm of chromosome 8 and the long arm of chromosome 14, with chromosomal breakage sites being at or near immunoglobulin and oncogene loci.

Instability of chromosomes also predisposes to the development of some malignancies. In certain autosomal recessive diseases such as ataxia-telangiectasia, Bloom syndrome, and Fanconi anemia, the cells have a tendency to **genetic instability**, ie, to chromosomal breakage and rearrangement in vitro. These diseases are associated with a high incidence of neoplasia, particularly leukemia and lymphoma.

Some chromosomal aberrations, better known for their effect on phenotype, also predispose to tumors. For example, patients with Down syndrome (trisomy 21) have a 20-fold increase in the risk of leukemia, 47,XXY males (Klinefelter syndrome) have a 30-fold increase in the risk of breast cancer, and XY phenotypic females have a heightened risk of developing ovarian cancer, primarily gonadoblastoma.

The indications for cytogenetic analysis of neoplasia continue to evolve. Not all tumors require study. However, in cases of tumors of unclear type (especially leukemias and lymphomas), with a strong family history of early neoplasia, or for certain tumors associated with potential generalized chromosomal defects (present in nonneoplastic cells), cytogenetic analysis should be strongly considered.

Acute Intermittent Porphyria

Essentials of Diagnosis

- Unexplained abdominal crisis, generally in young women.
- Acute peripheral or central nervous system dysfunction.
- Recurrent psychiatric illnesses.
- Hyponatremia.
- Porphobilinogen in the urine during an attack.

General Considerations

Though there are several different types of porphyrias, the one with the most serious consequences and the one that usually presents in adulthood is acute intermittent porphyria (AIP), which is inherited as an autosomal dominant, though it remains clinically silent in most patients who carry the trait. Clinical illness usually develops in women. Symptoms begin in the teens or 20s, but onset can begin after menopause in rare cases. The disorder is caused by partial deficiency of porphobilinogen deaminase activity, leading to increased excretion of aminolevulinic acid and porphobilinogen in the urine. The diagnosis may be elusive if not specifically considered. The characteristic abdominal pain may be due to abnormalities in autonomic innervation in the gut. In contrast to other forms of porphyria, cutaneous photosensitivity is absent in AIP. Attacks are precipitated by numerous factors, including drugs and intercurrent infections. Harmful and relatively safe drugs for use in treatment are listed in Table 40–1. Hyponatremia may be seen, due in part to inappropriate release of antidiuretic hormone, although gastrointestinal loss of sodium in some patients may be a contributing factor.

Table 40–1. Some of the "unsafe" and "probably safe" drugs used in the treatment of acute porphyrias.

Unsafe	**Probably Safe**
Alcohol	Acetaminophen
Alkylating agents	-Adrenergic blockers
Barbiturates	Amitriptyline
Carbamazepine	Aspirin
Chloroquine	Atropine
Chlorpropamide	Chloral hydrate

Clonidine	Chlordiazepoxide
Dapsone	Corticosteroids
Ergots	Diazepam
Erythromycin	Digoxin
Estrogens, synthetic	Diphenhydramine
Food additives	Guanethidine
Glutethimide	Hyoscine
Griseofulvin	Ibuprofen
Hydralazine	Imipramine
Ketamine	Insulin
Meprobamate	Lithium
Methyldopa	Naproxen
Metoclopramide	Nitrofurantoin
Nortriptyline	Opioid analgesics
Pentazocine	Penicillamine
Phenytoin	Penicillin and derivatives
Progestins	Phenothiazines
Pyrazinamide	Procaine
Rifampin	Streptomycin
Spironolactone	Succinylcholine
Succinimides	Tetracycline
Sulfonamides	Thiouracil

Theophylline	
Tolazamide	
Tolbutamide	
Valproic acid	

Clinical Findings

Symptoms and Signs

Patients show intermittent abdominal pain of varying severity, and in some instances it may so simulate acute abdomen as to lead to exploratory laparotomy. Because the origin of the abdominal pain is neurologic, there is an absence of fever and leukocytosis. Complete recovery between attacks is usual. Any part of the nervous system may be involved, with evidence for autonomic and peripheral neuropathy. Peripheral neuropathy may be symmetric or asymmetric and mild or profound; in the latter instance, it can even lead to quadriplegia with respiratory paralysis. Other central nervous system manifestations include seizures, psychosis, and abnormalities of the basal ganglia. Hyponatremia may further cause or exacerbate central nervous system manifestations.

Laboratory Findings

Often there is profound hyponatremia. The diagnosis can be confirmed by demonstrating an increased amount of porphobilinogen in the urine during an acute attack. Freshly voided urine is of normal color but may turn dark upon standing in light and air.

Most families have a different mutation in the porphobilinogen deaminase gene causing AIP. Mutations can be detected and used for presymptomatic and prenatal diagnosis.

Prevention

Avoidance of factors known to precipitate attacks of AIP—especially drugs—can reduce morbidity. Sulfonamides and barbiturates are the most common culprits; others are listed in Table 40–1) and on the Internet (www.drugs-porphyria.org). Starvation diets or prolonged fasting also cause attacks and so must be avoided. Hormonal changes during pregnancy can precipitate crises.

Treatment

Treatment with a high-carbohydrate diet diminishes the number of attacks in some patients and is a reasonable empiric gesture considering its benignity. Acute attacks may be life-threatening and require prompt diagnosis, withdrawal of the inciting agent (if possible), and treatment with analgesics and intravenous glucose and hematin. A minimum of 300 g of carbohydrate per day should be provided orally or intravenously. Electrolyte balance requires close attention. Hematin therapy is still evolving and should be undertaken with full recognition of adverse consequences, especially phlebitis and coagulopathy. The intravenous dosage is up to 4 mg/kg once or twice daily. Liver transplantation may provide an option for patients with disease poorly controlled by medical therapy.

When to Refer

- For management of severe abdominal pain, seizures, or psychosis.
- For preventive management when a patient with porphyria contemplates pregnancy.
- For genetic counseling and molecular diagnosis.

When to Admit

The patient should be hospitalized when he or she has an acute attack accompanied by mental status changes, seizure, or hyponatremia.

Alkaptonuria

Essentials of Diagnosis

- Ochronosis (gray-black discoloration of connective tissue, including the sclerae, ears, and cartilage).
- Characteristic radiologic changes in the spine, with radiodense intervertebral discs.
- Arthropathy.
- Urine darkens on standing.

Clinical Findings

Symptoms and Signs

Alkaptonuria is caused by a recessively inherited deficiency of the enzyme homogentisic acid oxidase. This acid derives from metabolism of both phenylalanine and tyrosine and is present in large amounts in the urine throughout the patient's life. An oxidation product accumulates slowly in cartilage throughout the body, leading to degenerative joint disease of the spine and peripheral joints. Indeed, examination of patients in the third and fourth decades shows a slight darkish blue color below the skin in areas overlying cartilage, such as in the ears, a phenomenon called **ochronosis.** In some patients, a more severe hyperpigmentation can be seen in the sclera, conjunctiva, and cornea. Accumulation of metabolites in heart valves can lead to aortic or mitral stenosis. A predisposition to coronary artery disease may also be present. Although the syndrome causes considerable morbidity, life expectancy is reduced only modestly. Symptoms are more often attributable to spondylitis with back pain, leading to a clinical picture difficult to distinguish from that of ankylosing spondylitis, though on radiographic assessment the sacroiliac joints are not fused in alkaptonuria.

Laboratory Findings

The diagnosis is established by demonstrating homogentisic acid in the urine, which turns black spontaneously on exposure to the air; this reaction is particularly noteworthy if the urine is alkaline or when alkali is added to a specimen. Molecular analysis of the homogentisic acid oxidase gene, recently mapped to chromosome 3, is available but not necessary for diagnosis.

Prevention

Carrier screening and prenatal diagnosis are possible by testing for genetic mutations.

Treatment

Treatment of the arthritis is similar to that for other arthropathies. Though, in theory, rigid dietary restriction might reduce accumulation of the pigment, this has not proved to be of practical benefit.

Perry MB et al. Musculoskeletal findings and disability in alkaptonuria. J Rheumatol. 2006 Nov;33(11):2280–5. [PMID: 16981292]

Down Syndrome

Essentials of Diagnosis

- Typical craniofacial features (flat occiput, epicanthal folds, large tongue).
- Mental retardation.
- Congenital heart disease (eg, atrioventricular canal

defects) in 50% of patients.
- Three copies of chromosome 21 (trisomy 21) or a chromosome rearrangement that results in three copies of a region of the long arm of chromosome 21.

Clinical Findings

Symptoms and Signs

Down syndrome is usually diagnosed at birth on the basis of the typical craniofacial features, hypotonia, and single palmar crease. Several serious problems that may be evident at birth or may develop early in childhood include duodenal atresia, congenital heart disease (especially atrioventricular canal defects), and hematologic malignancy. The intestinal and cardiac anomalies usually respond to surgery. A transient neonatal leukemia generally responds to conservative management. The incidences of both acute lymphoblastic and myeloid leukemias are increased in childhood. Intelligence varies across a wide spectrum. Many people with Down syndrome do well in sheltered workshops and group homes, but few achieve full independence in adulthood. Other frequent complications include atlanto-axial instability, celiac disease, and hypothyroidism. An Alzheimer-like dementia usually becomes evident in the fourth or fifth decade and, for those who survive childhood, accounts for a reduced life expectancy.

Laboratory Findings

Cytogenetic analysis should always be performed—even though most patients will have simple trisomy for chromosome 21—to detect unbalanced translocations; such patients may have a parent with a balanced translocation, and there will be a substantial recurrence risk of Down syndrome in future offspring of that parent and potentially that parent's relatives.

Prevention

The presence of a fetus with Down syndrome can be detected in many pregnancies in the first or early second trimester through screening maternal serum for -fetoprotein and other biomarkers ("multiple marker screening") and by detecting increased nuchal thickness and underdevelopment of the nasal bone on fetal ultrasound. The risk of bearing a child with Down syndrome increases exponentially with the age of the mother at conception and begins a marked rise after age 35. By age 45 years, a mother has one chance in 40 of having an affected child. The risk of other conditions associated with trisomy also increases, because of the predisposition of older oocytes to nondisjunction during meiosis. There is little risk of trisomy associated with increased paternal age. However, older men do have an increased risk of fathering a child with a new autosomal dominant condition. But because there are so many distinct conditions, the chance of fathering an offspring with any given one is extremely small.

Treatment

Duodenal atresia should be treated surgically. Congenital heart disease should be treated as in any other patient. No medical treatment has been proven to affect the intellectual capacity.

When to Refer

- For comprehensive evaluation of infants to investigate congenital heart disease, hematologic malignancy, and duodenal atresia.
- For genetic counseling of the parents.
- For signs of dementia in an adult patient.

When to Admit

An affected young patient should be hospitalized when he or she has failure to thrive, regurgitation, breathlessness, or easy bruising.

Fragile X Mental Retardation

Essentials of Diagnosis

- Expanded trinucleotide repeat in the *FMR1* gene.
- Mental retardation and autism in males.
- Large testes after puberty.
- Learning disabilities or mental retardation in females.
- Premature ovarian failure.
- Late-onset tremor and ataxia in males and females with moderate trinucleotide repeat expansion (premutation carriers).

Clinical Findings

Symptoms and Signs

This X-linked condition accounts for more cases of mental retardation in males than any condition except Down syndrome; about 1 in 4000 to 1 in 6000 males is affected; the condition also affects intellectual function in females, although less severely and about 50% less frequently than in males.

Laboratory Findings

The first marker for this condition was a small gap, or fragile site, evident near the tip of the long arm of the X chromosome. Subsequently, the condition was found to be due to expansion of a trinucleotide repeat (CGG) near a gene called *FMR1*. All individuals have some CGG repeats in this location, but as the number increases beyond 52, the chances of further expansion during spermatogenesis or oogenesis increase.

Being born with one *FMR1* allele with 200 or more repeats results in mental retardation in most men, and in about 60% of women. The more repeats, the greater the likelihood that further expansion will occur during gametogenesis; this results in anticipation, in which the disorder can worsen from one generation to the next. Affected (heterozygous) young women show no physical signs other than early menopause, but they may have learning difficulties or frank retardation. Affected males show macroorchidism (enlarged testes) after puberty, large ears and a prominent jaw, a high-pitched voice, autistic characteristics, and mental retardation. Some males show evidence of a mild connective tissue defect, with joint hypermobility and mitral valve prolapse.

Women who are premutation carriers (55–200 CGG repeats) are at increased risk for premature ovarian failure and mild cognitive or behavioral abnormalities. Male and female premutation carriers are at risk for the development of tremor and ataxia beyond middle age (fragile-X tremor-ataxia syndrome, FXTAS). Changes in the cerebellar white matter on MRI may be evident before symptoms appear. Because of the relatively high prevalence of premutation carriers in the general population, older people in whom any of these behavioral or neurologic problems develop should undergo testing of the *FMR1* locus.

Prevention

DNA diagnosis for the number of repeats has supplanted cytogenetic analysis for both clinical and prenatal diagnosis. This should be done on any male or female who has unexplained mental retardation.

Treatment

No specific treatments have been developed. Attention-deficit and hyperactivity symptoms can respond to standard therapy, and a recent trial of L-acetylcarnitine showed promise.

When to Refer

- For otherwise unexplained mental retardation or learning difficulties in boys and girls.
- For otherwise unexplained tremor or ataxia in middle-aged individuals.
- For premature ovarian failure.
- For genetic counseling.

Gaucher Disease

Essentials of Diagnosis

- Deficiency of -glucocerebrosidase.
- Anemia and thrombocytopenia.
- Hypersplenism.
- Pathologic fractures.

Clinical Findings

Symptoms and Signs

Gaucher disease has an autosomal recessive pattern of inheritance. A deficiency of -glucocerebrosidase causes an accumulation of sphingolipid within phagocytic cells throughout the body. Anemia and thrombocytopenia are common and may be symptomatic; both are due primarily to hypersplenism, but marrow infiltration with Gaucher cells may be a contributing factor. Cortical erosions of bones, especially the vertebrae and femur, are due to local infarctions, but the mechanism is unclear. Episodes of bone pain (termed "crises") are reminiscent of those in sickle cell disease. A hip fracture in a patient with a palpable spleen—especially in a Jewish person of Eastern European origin—suggests the possibility of Gaucher disease.

Two uncommon forms of Gaucher disease, called type II and type III, involve neurologic accumulation of sphingolipid and a variety of neurologic problems. Type II is of infantile onset and has a poor prognosis. Heterozygotes for Gaucher disease may be at increased risk for developing Parkinson disease.

Laboratory Findings

Bone marrow aspirates reveal typical Gaucher cells, which have an eccentric nucleus and periodic acid–Schiff (PAS)-positive inclusions, along with wrinkled cytoplasm and inclusion bodies of a fibrillar type. In addition, the serum acid phosphatase is elevated. Definitive diagnosis requires the demonstration of deficient glucocerebrosidase activity in leukocytes. Over 200 mutations have been found to cause Gaucher disease and some are highly predictive of the neuronopathic forms. Thus, mutation detection, especially in a young person, is of potential value. Only four mutations in glucocerebrosidase account for more than 90% of the disease among Ashkenazi Jews, in whom the carrier frequency is 1:15.

Prevention

Most clinical complications can be prevented by early institution of enzyme replacement therapy. Carrier screening, especially among Ashkenazi Jews, detects those couples at 25% risk of having an affected child. Prenatal diagnosis through mutation analysis is feasible.

Treatment

For many years, treatment was supportive and included splenectomy for thrombocytopenia secondary to platelet sequestration. A recombinant form of the enzyme glucocerebrosidase (imiglucerase) for intravenous administration on a regular basis now permits a reduction in total body stores of glycolipid and improvement in orthopedic and hematologic manifestations.

Unfortunately, the neurologic manifestations of types II and III have not improved with enzyme replacement therapy. The major drawback is the exceptional cost of imiglucerase, which can exceed $350,000 per year for a severely affected patient. Administration of less enzyme (30 units/kg per month) is effective for most adults and reduces the cost to about $100,000–150,000 annually. Alternative or complementary therapies, including methods to reduce substrate and to provide a chaperone for a defective enzyme, are being developed.

Disorders of Homocysteine Metabolism

Essentials of Diagnosis

- For homocystinuria, dislocated ocular lenses.
- Elevated homocysteine in the urine or plasma.

General Considerations

Considerable evidence has accumulated to support the 20-year-old observation that patients with clinical and angiographic evidence of coronary artery disease tend to have higher levels of plasma homocysteine than persons without coronary artery disease. The relationship has been extended to cerebrovascular and peripheral vascular diseases. Although this effect was initially thought to be due at least in part to heterozygotes for cystathionine -synthase deficiency (see below), there is little supporting evidence. Rather, the major factor leading to hyperhomocysteinemia is folate deficiency. Pyridoxine (vitamin B_6) and vitamin B_{12} are also important in the metabolism of methionine, and deficiency of any of these vitamins can lead to accumulation of homocysteine. A number of genes influence utilization of these vitamins and can predispose to deficiency. For example, having one—and especially two—copies of an allele that causes thermolability of methylene tetrahydrofolate reductase predisposes people to elevated fasting homocysteine levels. However, both nutritional and most genetic deficiencies of these vitamins can be corrected by dietary supplementation of folic acid and, if serum levels are low, vitamins B_6 and B_{12}. In the United States, cereal grains are now fortified with folic acid. Studies are ongoing to determine the long-term utility of routine vitamin supplementation in people at risk for arterial occlusive disease, but many workers in this field recommend, at a minimum, taking 1 mg of folic acid per day. Recent studies showed that therapy with B vitamins lowered homocysteine levels significantly, but did not reduce the risk of either venous thromboembolism or complications of coronary artery disease. The role of lowering homocysteine as primary prevention for sequelae of atherosclerosis is still undetermined. Hyperhomocysteinemia occurs with end-stage chronic kidney disease.

Clinical Findings

Symptoms and Signs

Homocystinuria in its classic form is caused by cystathionine -synthase deficiency and exhibits an autosomal recessive pattern of inheritance. This results in extreme elevations of plasma and urinary homocystine levels, a basis for diagnosis of this disorder. Homocystinuria is similar in certain superficial aspects to Marfan syndrome, since patients may have a similar body habitus and ectopia lentis is almost always present. However, mental retardation is often present in homocystinuria, and the cardiovascular events are those of repeated venous and arterial thromboses whose precise cause remains obscure. Life expectancy is reduced, especially in untreated and pyridoxine-unresponsive patients; myocardial infarction, stroke, and pulmonary embolism are the most common causes of death. This condition is diagnosed by newborn screening for hypermethioninemia; however, pyridoxine-responsive infants may not be detected. The diagnosis should be suspected in patients in the second and third decades of life who show evidence of arterial or venous thromboses and have no other risk factors.

Laboratory Findings

Although many mutations have been identified in the cystathionine -synthase gene, amino acid analysis of plasma remains the most appropriate diagnostic test. Patients should be studied after they have been off folate or pyridoxine supplementation for at least 1 week. Relatively few laboratories currently provide highly reliable assays for homocysteine. Processing of the specimen is crucial to obtain accurate results. The plasma must be separated within 30 minutes; otherwise, blood cells release the amino acid and the measurement will then be artificially elevated.

Prevention

About 50% of patients have a form of cystathionine -synthase deficiency that improves biochemically and clinically through pharmacologic doses of pyridoxine and folate. For these patients, treatment from infancy can prevent retardation and the other clinical problems. Patients who are pyridoxine nonresponders must be treated with a dietary reduction in methionine and supplementation of cysteine, also from infancy. The vitamin betaine is also useful in reducing plasma methionine levels by facilitating a metabolic pathway that bypasses the defective enzyme.

Treatment

Patients with classic homocystinuria who have suffered venous thrombosis receive anticoagulation therapy, but there are no studies to support prophylactic use of warfarin or antiplatelet agents.

Klinefelter Syndrome

Essentials of Diagnosis

- Males with hypogonadism and small testes.
- 47,XXY karyotype.

Clinical Findings

Symptoms and Signs

Boys with an extra X chromosome are normal in appearance before puberty; thereafter, they have disproportionately long legs and arms, a female escutcheon, gynecomastia, and small testes. Infertility is due to azoospermia; the seminiferous tubules are hyalinized. The diagnosis is often not made until a couple is evaluated for inability to conceive. Mental retardation is somewhat more common than in the general population. Many men with Klinefelter syndrome have learning problems. However, their intelligence usually tests within the broad range of normal. As adults, detailed psychometric testing may reveal a deficiency in executive skills. The risk of breast cancer and diabetes mellitus is much higher in men with Klinefelter syndrome than in 46,XY men.

Laboratory Findings

Low serum testosterone is common. The karyotype is typically 47,XXY.

Prevention

Screening for cancer, especially of the breast, and for glucose intolerance are indicated.

Treatment

Treatment with testosterone after puberty is advisable but will not restore fertility. However, men with Klinefelter syndrome have had mature sperm aspirated from their testes and injected into oocytes, resulting in fertilization. After the blastocysts have been implanted into the uterus of a partner, conception has resulted. However, men with Klinefelter syndrome do have an increased risk for aneuploidy in sperm, and therefore chromosome analysis of a blastocyst should be considered before implantation.

Bojesen A et al. The metabolic syndrome is frequent in Klinefelter's syndrome and is associated with abdominal obesity and hypogonadism. Diabetes Care. 2006 Jul;29(7):1591–8. [PMID: 16801584]

Marfan Syndrome

Essentials of Diagnosis

- Disproportionately tall stature, thoracic deformity, and joint laxity or contractures.
- Ectopia lentis and myopia.
- Aortic dilation and dissection.
- Mitral valve prolapse.

General Considerations

Marfan syndrome, a systemic connective tissue disease, has an autosomal dominant pattern of inheritance. It is characterized by abnormalities of the skeletal, ocular, and cardiovascular systems; spontaneous pneumothorax; dural ectasia; and striae atrophicae. Of most concern is disease of the ascending aorta, which begins as a dilated aortic root. Histology of the aorta shows diffuse medial degeneration. Mitral valve leaflets are also abnormal and mitral prolapse and regurgitation may be present, often with elongated chordae tendineae, which on occasion may rupture.

Clinical Findings

Symptoms and Signs

Affected patients are typically tall, with particularly long arms, legs, and digits (arachnodactyly). However, there can be wide variability in the clinical presentation. Commonly, scoliosis and anterior chest deformity, such as pectus excavatum, are found. Ectopia lentis may lead to severe myopia and retinal detachment. Mitral valve prolapse is seen in about 85% of patients. Aortic root dilation is common and leads to aortic regurgitation or dissection with rupture. To diagnose Marfan syndrome, people with an affected relative need features in at least two systems. People with no family history need features in the skeletal system, two other systems, and one of the major criteria of ectopia lentis, dilation of the aortic root, or aortic dissection. Patients with homocystinuria due to cystathionine synthase deficiency also have dislocated lenses; tall, disproportionate stature; and thoracic deformity. They tend to have below normal intelligence, stiff joints, and a predisposition to arterial and venous occlusive disease. Males with Klinefelter syndrome do not show the typical ocular or cardiovascular features of Marfan syndrome and are generally sporadic occurrences in the family.

Laboratory Findings

Mutations in the fibrillin gene (*FBN1*) on chromosome 15 cause Marfan syndrome. Nonetheless, no simple laboratory test is available to support the diagnosis in questionable cases because related conditions may also be due to defects in fibrillin. The nature of the *FBN1* mutation has little predictive value in terms of prognosis. The pathogenesis of Marfan syndrome involves aberrant regulation of transforming growth factor (TGF) activity. Mutations in either of two receptors for TGF (TGFBR1 and TGFBR2) can cause conditions that resemble Marfan syndrome in terms of aortic aneurysm and dissection and autosomal dominant inheritance.

Prevention

There is prenatal and presymptomatic diagnosis for patients in whom the molecular defect in fibrillin has been found and for large enough families in whom linkage analysis using polymorphic markers around *FBN1* can be performed.

Treatment

Children with Marfan syndrome require regular ophthalmologic surveillance to correct visual acuity and thus prevent amblyopia, and annual orthopedic consultation for diagnosis of scoliosis at an early enough stage so that bracing might delay progression. Patients of all ages require echocardiography at least annually to monitor aortic diameter and mitral valve function. All patients should use standard endocarditis prophylaxis.

Long-term -adrenergic blockade, titrated to individual tolerance but enough to produce a negative inotropic effect (atenolol, 1–2 mg/kg), retards the rate of aortic dilation. A clinical trial comparing the effectiveness of atenolol and losartan, a drug that reduces activity of TGF- , is underway. Restriction from vigorous physical exertion protects from aortic dissection. Prophylactic replacement of the aortic root with a composite graft when the diameter reaches 45–50 mm in an adult (normal: < 40 mm) prolongs life. A procedure to reimplant the patient's native aortic valve and replace just the aneurysmal sinuses of Valsalva shows promise and also avoids the need for lifelong anticoagulation.

Prognosis

People with Marfan syndrome who are untreated commonly die in the fourth or fifth decade from aortic dissection or congestive heart failure secondary to aortic regurgitation. However, because of earlier diagnosis, lifestyle modifications, beta-adrenergic blockade, and prophylactic aortic surgery, life expectancy has increased by several decades in the past 25 years.

When to Refer

- For detailed ophthalmologic examination.
- For at least annual cardiologic evaluation.
- For moderate scoliosis.
- For pregnancy in a woman with Marfan syndrome.
- For genetic counseling.

When to Admit

Any patient with Marfan syndrome in whom severe or unusual chest pain develops should be hospitalized to exclude pneumothorax and aortic dissection.

Hereditary Hemorrhagic Telangiectasia

Essentials of Diagnosis

- Recurrent epistaxis.
- Mucocutaneous telangiectases.
- Visceral arteriovenous malformations (especially lung, liver, brain, bowel).

Clinical Findings

Symptoms and Signs

Hereditary hemorrhagic telangiectasia (HHT), formerly termed "Osler-Weber-Rendu syndrome, " is an autosomal dominant disorder of development of the vasculature. Epistaxis may begin in childhood or later in adolescence. Punctate telangiectases of the lips, tongue, fingers, and skin generally appear in later childhood and adolescence. Arteriovenous malformations (AVMs) can occur at any age in the brain, lungs, and liver. Bleeding from the gastrointestinal tract is due to mucosal vascular malformations and usually is not a problem until mid-adult years or later. Pulmonary AVMs can cause hypoxemia (with peripheral cyanosis, dyspnea, and clubbing) and right-to-left shunting (with embolic stroke or brain abscess). The criteria for diagnosis require presence of three of the following four features: (1) recurrent epistaxis, (2) visceral AVMs, (3) mucocutaneous telangiectases, and (4) being the near relative of a clearly affected individual. Mutation analysis can be used for presymptomatic diagnosis or exclusion of the worry of HHT.

Laboratory Findings

MR or CT arteriography detects AVMs. Mutations in at least five genes can cause HHT. Three have been identified and molecular analysis to identify them is available; these mutations in *ENG*, *ALK1* and *SMAD4* account for about 70% of families with HHT.

Prevention

Embolization of pulmonary AVMs reduces the risk of stroke and brain abscess. Treatment of brain AVMs reduces the risk of hemorrhagic stroke. All patients with HHT should practice routine endocarditis prophylaxis. All intravenous lines should have an air-filter to prevent embolization of an air bubble. Prenatal diagnosis through mutation detection is possible.

Treatment

All patients in whom the diagnosis of HHT is considered should have an MRI of the brain with contrast. A contrast echocardiogram will detect most pulmonary AVMs when "bubbles" appear on the left side of the heart after 3–6 cardiac cycles. A positive contrast echocardiogram should be followed by a high-resolution CT angiogram for localization of pulmonary AVMs. Patients who have AVMs with a feeding artery of 1 mm diameter or greater should undergo embolization. After successful embolization of all treatable pulmonary AVMs, the CT angiogram should be repeated in 3 years. A person with a negative contrast echocardiogram should have the test repeated every 5 years.

Acute Intermittent Porphyria

Essentials of Diagnosis

- Unexplained abdominal crisis, generally in young women.
- Acute peripheral or central nervous system dysfunction.
- Recurrent psychiatric illnesses.
- Hyponatremia.
- Porphobilinogen in the urine during an attack.

General Considerations

Though there are several different types of porphyrias, the one with the most serious consequences and the one that usually presents in adulthood is acute intermittent porphyria (AIP), which is inherited as an autosomal dominant, though it remains clinically silent in most patients who carry the trait. Clinical illness usually develops in women. Symptoms begin in the teens or 20s, but onset can begin after menopause in rare cases. The disorder is caused by partial deficiency of porphobilinogen deaminase activity, leading to increased excretion of aminolevulinic acid and porphobilinogen in the urine. The diagnosis may be elusive if not specifically considered. The characteristic abdominal pain may be due to abnormalities in autonomic innervation in the gut. In contrast to other forms of porphyria, cutaneous photosensitivity is absent in AIP. Attacks are precipitated by numerous factors, including drugs and intercurrent infections. Harmful and relatively safe drugs for use in treatment are listed in Table 40–1. Hyponatremia may be seen, due in part to inappropriate release of antidiuretic hormone, although gastrointestinal loss of sodium in some patients may be a contributing factor.

Table 40–1. Some of the "unsafe" and "probably safe" drugs used in the treatment of acute porphyrias.

Unsafe	**Probably Safe**
Alcohol	Acetaminophen
Alkylating agents	-Adrenergic blockers
Barbiturates	Amitriptyline
Carbamazepine	Aspirin
Chloroquine	Atropine
Chlorpropamide	Chloral hydrate
Clonidine	Chlordiazepoxide
Dapsone	Corticosteroids
Ergots	Diazepam

Erythromycin	Digoxin
Estrogens, synthetic	Diphenhydramine
Food additives	Guanethidine
Glutethimide	Hyoscine
Griseofulvin	Ibuprofen
Hydralazine	Imipramine
Ketamine	Insulin
Meprobamate	Lithium
Methyldopa	Naproxen
Metoclopramide	Nitrofurantoin
Nortriptyline	Opioid analgesics
Pentazocine	Penicillamine
Phenytoin	Penicillin and derivatives
Progestins	Phenothiazines
Pyrazinamide	Procaine
Rifampin	Streptomycin
Spironolactone	Succinylcholine
Succinimides	Tetracycline
Sulfonamides	Thiouracil
Theophylline	
Tolazamide	
Tolbutamide	

Valproic acid	

Clinical Findings

Symptoms and Signs

Patients show intermittent abdominal pain of varying severity, and in some instances it may so simulate acute abdomen as to lead to exploratory laparotomy. Because the origin of the abdominal pain is neurologic, there is an absence of fever and leukocytosis. Complete recovery between attacks is usual. Any part of the nervous system may be involved, with evidence for autonomic and peripheral neuropathy. Peripheral neuropathy may be symmetric or asymmetric and mild or profound; in the latter instance, it can even lead to quadriplegia with respiratory paralysis. Other central nervous system manifestations include seizures, psychosis, and abnormalities of the basal ganglia. Hyponatremia may further cause or exacerbate central nervous system manifestations.

Laboratory Findings

Often there is profound hyponatremia. The diagnosis can be confirmed by demonstrating an increased amount of porphobilinogen in the urine during an acute attack. Freshly voided urine is of normal color but may turn dark upon standing in light and air.

Most families have a different mutation in the porphobilinogen deaminase gene causing AIP. Mutations can be detected and used for presymptomatic and prenatal diagnosis.

Prevention

Avoidance of factors known to precipitate attacks of AIP—especially drugs—can reduce morbidity. Sulfonamides and barbiturates are the most common culprits; others are listed in Table 40–1) and on the Internet (www.drugs-porphyria.org). Starvation diets or prolonged fasting also cause attacks and so must be avoided. Hormonal changes during pregnancy can precipitate crises.

Treatment

Treatment with a high-carbohydrate diet diminishes the number of attacks in some patients and is a reasonable empiric gesture considering its benignity. Acute attacks may be life-threatening and require prompt diagnosis, withdrawal of the inciting agent (if possible), and treatment with analgesics and intravenous glucose and hematin. A minimum of 300 g of carbohydrate per day should be provided orally or intravenously. Electrolyte balance requires close attention. Hematin therapy is still evolving and should be undertaken with full recognition of adverse consequences, especially phlebitis and coagulopathy. The intravenous dosage is up to 4 mg/kg once or twice daily. Liver transplantation may provide an option for patients with disease poorly controlled by medical therapy.

When to Refer

- For management of severe abdominal pain, seizures, or psychosis.
- For preventive management when a patient with porphyria contemplates pregnancy.
- For genetic counseling and molecular diagnosis.

When to Admit

The patient should be hospitalized when he or she has an acute attack accompanied by mental status changes, seizure, or hyponatremia.

Alkaptonuria

Essentials of Diagnosis

- Ochronosis (gray-black discoloration of connective tissue, including the sclerae, ears, and cartilage).
- Characteristic radiologic changes in the spine, with radiodense intervertebral discs.
- Arthropathy.
- Urine darkens on standing.

Clinical Findings

Symptoms and Signs

Alkaptonuria is caused by a recessively inherited deficiency of the enzyme homogentisic acid oxidase. This acid derives from metabolism of both phenylalanine and tyrosine and is present in large amounts in the urine throughout the patient's life. An oxidation product accumulates slowly in cartilage throughout the body, leading to degenerative joint disease of the spine and peripheral joints. Indeed, examination of patients in the third and fourth decades shows a slight darkish blue color below the skin in areas overlying cartilage, such as in the ears, a phenomenon called **ochronosis.** In some patients, a more severe hyperpigmentation can be seen in the sclera, conjunctiva, and cornea. Accumulation of metabolites in heart valves can lead to aortic or mitral stenosis. A predisposition to coronary artery disease may also be present. Although the syndrome causes considerable morbidity, life expectancy is reduced only modestly. Symptoms are more often attributable to spondylitis with back pain, leading to a clinical picture difficult to distinguish from that of ankylosing spondylitis, though on radiographic assessment the sacroiliac joints are not fused in alkaptonuria.

Laboratory Findings

The diagnosis is established by demonstrating homogentisic acid in the urine, which turns black spontaneously on exposure to the air; this reaction is particularly noteworthy if the urine is alkaline or when alkali is added to a specimen. Molecular analysis of the homogentisic acid oxidase gene, recently mapped to chromosome 3, is available but not necessary for diagnosis.

Prevention

Carrier screening and prenatal diagnosis are possible by testing for genetic mutations.

Treatment

Treatment of the arthritis is similar to that for other arthropathies. Though, in theory, rigid dietary restriction might reduce accumulation of the pigment, this has not proved to be of practical benefit.

Perry MB et al. Musculoskeletal findings and disability in alkaptonuria. J Rheumatol. 2006 Nov;33(11):2280–5. [PMID: 16981292]

Down Syndrome

Essentials of Diagnosis

- Typical craniofacial features (flat occiput, epicanthal folds, large tongue).
- Mental retardation.
- Congenital heart disease (eg, atrioventricular canal defects) in 50% of patients.
- Three copies of chromosome 21 (trisomy 21) or a chromosome rearrangement that results in three

copies of a region of the long arm of chromosome 21.

Clinical Findings

Symptoms and Signs

Down syndrome is usually diagnosed at birth on the basis of the typical craniofacial features, hypotonia, and single palmar crease. Several serious problems that may be evident at birth or may develop early in childhood include duodenal atresia, congenital heart disease (especially atrioventricular canal defects), and hematologic malignancy. The intestinal and cardiac anomalies usually respond to surgery. A transient neonatal leukemia generally responds to conservative management. The incidences of both acute lymphoblastic and myeloid leukemias are increased in childhood. Intelligence varies across a wide spectrum. Many people with Down syndrome do well in sheltered workshops and group homes, but few achieve full independence in adulthood. Other frequent complications include atlanto-axial instability, celiac disease, and hypothyroidism. An Alzheimer-like dementia usually becomes evident in the fourth or fifth decade and, for those who survive childhood, accounts for a reduced life expectancy.

Laboratory Findings

Cytogenetic analysis should always be performed—even though most patients will have simple trisomy for chromosome 21—to detect unbalanced translocations; such patients may have a parent with a balanced translocation, and there will be a substantial recurrence risk of Down syndrome in future offspring of that parent and potentially that parent's relatives.

Prevention

The presence of a fetus with Down syndrome can be detected in many pregnancies in the first or early second trimester through screening maternal serum for -fetoprotein and other biomarkers ("multiple marker screening") and by detecting increased nuchal thickness and underdevelopment of the nasal bone on fetal ultrasound. The risk of bearing a child with Down syndrome increases exponentially with the age of the mother at conception and begins a marked rise after age 35. By age 45 years, a mother has one chance in 40 of having an affected child. The risk of other conditions associated with trisomy also increases, because of the predisposition of older oocytes to nondisjunction during meiosis. There is little risk of trisomy associated with increased paternal age. However, older men do have an increased risk of fathering a child with a new autosomal dominant condition. But because there are so many distinct conditions, the chance of fathering an offspring with any given one is extremely small.

Treatment

Duodenal atresia should be treated surgically. Congenital heart disease should be treated as in any other patient. No medical treatment has been proven to affect the intellectual capacity.

When to Refer

- For comprehensive evaluation of infants to investigate congenital heart disease, hematologic malignancy, and duodenal atresia.
- For genetic counseling of the parents.
- For signs of dementia in an adult patient.

When to Admit

An affected young patient should be hospitalized when he or she has failure to thrive, regurgitation, breathlessness, or easy bruising.

Fragile X Mental Retardation

Essentials of Diagnosis

- Expanded trinucleotide repeat in the *FMR1* gene.
- Mental retardation and autism in males.
- Large testes after puberty.
- Learning disabilities or mental retardation in females.
- Premature ovarian failure.

- Late-onset tremor and ataxia in males and females with moderate trinucleotide repeat expansion (premutation carriers).

Clinical Findings

Symptoms and Signs

This X-linked condition accounts for more cases of mental retardation in males than any condition except Down syndrome; about 1 in 4000 to 1 in 6000 males is affected; the condition also affects intellectual function in females, although less severely and about 50% less frequently than in males.

Laboratory Findings

The first marker for this condition was a small gap, or fragile site, evident near the tip of the long arm of the X chromosome. Subsequently, the condition was found to be due to expansion of a trinucleotide repeat (CGG) near a gene called *FMR1*. All individuals have some CGG repeats in this location, but as the number increases beyond 52, the chances of further expansion during spermatogenesis or oogenesis increase.

Being born with one *FMR1* allele with 200 or more repeats results in mental retardation in most men, and in about 60% of women. The more repeats, the greater the likelihood that further expansion will occur during gametogenesis; this results in anticipation, in which the disorder can worsen from one generation to the next. Affected (heterozygous) young women show no physical signs other than early menopause, but they may have learning difficulties or frank retardation. Affected males show macroorchidism (enlarged testes) after puberty, large ears and a prominent jaw, a high-pitched voice, autistic characteristics, and mental retardation. Some males show evidence of a mild connective tissue defect, with joint hypermobility and mitral valve prolapse.

Women who are premutation carriers (55–200 CGG repeats) are at increased risk for premature ovarian failure and mild cognitive or behavioral abnormalities. Male and female premutation carriers are at risk for the development of tremor and ataxia beyond middle age (fragile-X tremor-ataxia syndrome, FXTAS). Changes in the cerebellar white matter on MRI may be evident before symptoms appear. Because of the relatively high prevalence of premutation carriers in the general population, older people in whom any of these behavioral or neurologic problems develop should undergo testing of the *FMR1* locus.

Prevention

DNA diagnosis for the number of repeats has supplanted cytogenetic analysis for both clinical and prenatal diagnosis. This should be done on any male or female who has unexplained mental retardation.

Treatment

No specific treatments have been developed. Attention-deficit and hyperactivity symptoms can respond to standard therapy, and a recent trial of L-acetylcarnitine showed promise.

When to Refer

- For otherwise unexplained mental retardation or learning difficulties in boys and girls.
- For otherwise unexplained tremor or ataxia in middle-aged individuals.
- For premature ovarian failure.
- For genetic counseling.

Gaucher Disease

Essentials of Diagnosis

- Deficiency of -glucocerebrosidase.
- Anemia and thrombocytopenia.
- Hypersplenism.
- Pathologic fractures.

Clinical Findings

Symptoms and Signs

Gaucher disease has an autosomal recessive pattern of inheritance. A deficiency of -glucocerebrosidase causes an accumulation of sphingolipid within phagocytic cells throughout the body. Anemia and thrombocytopenia are common and may be symptomatic; both are due primarily to hypersplenism, but marrow infiltration with Gaucher cells may be a contributing factor. Cortical erosions of bones, especially the vertebrae and femur, are due to local infarctions, but the mechanism is unclear. Episodes of bone pain (termed "crises") are reminiscent of those in sickle cell disease. A hip fracture in a patient with a palpable spleen—especially in a Jewish person of Eastern European origin—suggests the possibility of Gaucher disease.

Two uncommon forms of Gaucher disease, called type II and type III, involve neurologic accumulation of sphingolipid and a variety of neurologic problems. Type II is of infantile onset and has a poor prognosis. Heterozygotes for Gaucher disease may be at increased risk for developing Parkinson disease.

Laboratory Findings

Bone marrow aspirates reveal typical Gaucher cells, which have an eccentric nucleus and periodic acid–Schiff (PAS)-positive inclusions, along with wrinkled cytoplasm and inclusion bodies of a fibrillar type. In addition, the serum acid phosphatase is elevated. Definitive diagnosis requires the demonstration of deficient glucocerebrosidase activity in leukocytes. Over 200 mutations have been found to cause Gaucher disease and some are highly predictive of the neuronopathic forms. Thus, mutation detection, especially in a young person, is of potential value. Only four mutations in glucocerebrosidase account for more than 90% of the disease among Ashkenazi Jews, in whom the carrier frequency is 1:15.

Prevention

Most clinical complications can be prevented by early institution of enzyme replacement therapy. Carrier screening, especially among Ashkenazi Jews, detects those couples at 25% risk of having an affected child. Prenatal diagnosis through mutation analysis is feasible.

Treatment

For many years, treatment was supportive and included splenectomy for thrombocytopenia secondary to platelet sequestration. A recombinant form of the enzyme glucocerebrosidase (imiglucerase) for intravenous administration on a regular basis now permits a reduction in total body stores of glycolipid and improvement in orthopedic and hematologic manifestations. Unfortunately, the neurologic manifestations of types II and III have not improved with enzyme replacement therapy. The major drawback is the exceptional cost of imiglucerase, which can exceed $350,000 per year for a severely affected patient. Administration of less enzyme

(30 units/kg per month) is effective for most adults and reduces the cost to about $100,000–150,000 annually. Alternative or complementary therapies, including methods to reduce substrate and to provide a chaperone for a defective enzyme, are being developed.

Disorders of Homocysteine Metabolism

Essentials of Diagnosis

- For homocystinuria, dislocated ocular lenses.
- Elevated homocysteine in the urine or plasma.

General Considerations

Considerable evidence has accumulated to support the 20-year-old observation that patients with clinical and angiographic evidence of coronary artery disease tend to have higher levels of plasma homocysteine than persons without coronary artery disease. The relationship has been extended to cerebrovascular and peripheral vascular diseases. Although this effect was initially thought to be due at least in part to heterozygotes for cystathionine -synthase deficiency (see below), there is little supporting evidence. Rather, the major factor leading to hyperhomocysteinemia is folate deficiency. Pyridoxine (vitamin B_6) and vitamin B_{12} are also important in the metabolism of methionine, and deficiency of any of these vitamins can lead to accumulation of homocysteine. A number of genes influence utilization of these vitamins and can predispose to deficiency. For example, having one—and especially two—copies of an allele that causes thermolability of methylene tetrahydrofolate reductase predisposes people to elevated fasting homocysteine levels. However, both nutritional and most genetic deficiencies of these vitamins can be corrected by dietary supplementation of folic acid and, if serum levels are low, vitamins B_6 and B_{12}. In the United States, cereal grains are now fortified with folic acid. Studies are ongoing to determine the long-term utility of routine vitamin supplementation in people at risk for arterial occlusive disease, but many workers in this field recommend, at a minimum, taking 1 mg of folic acid per day. Recent studies showed that therapy with B vitamins lowered homocysteine levels significantly, but did not reduce the risk of either venous thromboembolism or complications of coronary artery disease. The role of lowering homocysteine as primary prevention for sequelae of atherosclerosis is still undetermined. Hyperhomocysteinemia occurs with end-stage chronic kidney disease.

Clinical Findings

Symptoms and Signs

Homocystinuria in its classic form is caused by cystathionine -synthase deficiency and exhibits an autosomal recessive pattern of inheritance. This results in extreme elevations of plasma and urinary homocystine levels, a basis for diagnosis of this disorder. Homocystinuria is similar in certain superficial aspects to

Marfan syndrome, since patients may have a similar body habitus and ectopia lentis is almost always present. However, mental retardation is often present in homocystinuria, and the cardiovascular events are those of repeated venous and arterial thromboses whose precise cause remains obscure. Life expectancy is reduced, especially in untreated and pyridoxine-unresponsive patients; myocardial infarction, stroke, and pulmonary embolism are the most common causes of death. This condition is diagnosed by newborn screening for hypermethioninemia; however, pyridoxine-responsive infants may not be detected. The diagnosis should be suspected in patients in the second and third decades of life who show evidence of arterial or venous thromboses and have no other risk factors.

Laboratory Findings

Although many mutations have been identified in the cystathionine -synthase gene, amino acid analysis of plasma remains the most appropriate diagnostic test. Patients should be studied after they have been off folate or pyridoxine supplementation for at least 1 week. Relatively few laboratories currently provide highly reliable assays for homocysteine. Processing of the specimen is crucial to obtain accurate results. The plasma must be separated within 30 minutes; otherwise, blood cells release the amino acid and the measurement will then be artificially elevated.

Prevention

About 50% of patients have a form of cystathionine -synthase deficiency that improves biochemically and clinically through pharmacologic doses of pyridoxine and folate. For these patients, treatment from infancy can prevent retardation and the other clinical problems. Patients who are pyridoxine nonresponders must be treated with a dietary reduction in methionine and supplementation of cysteine, also from infancy. The vitamin betaine is also useful in reducing plasma methionine levels by facilitating a metabolic pathway that bypasses the defective enzyme.

Treatment

Patients with classic homocystinuria who have suffered venous thrombosis receive anticoagulation therapy, but there are no studies to support prophylactic use of warfarin or antiplatelet agents.

Klinefelter Syndrome

Essentials of Diagnosis

- Males with hypogonadism and small testes.
- 47,XXY karyotype.

Clinical Findings

Symptoms and Signs

Boys with an extra X chromosome are normal in appearance before puberty; thereafter, they have disproportionately long legs and arms, a female escutcheon, gynecomastia, and small testes. Infertility is due to azoospermia; the seminiferous tubules are hyalinized. The diagnosis is often not made until a couple is evaluated for inability to conceive. Mental retardation is somewhat more common than in the general population. Many men with Klinefelter syndrome have learning problems. However, their intelligence usually tests within the broad range of normal. As adults, detailed psychometric testing may reveal a deficiency in executive skills. The risk of breast cancer and diabetes mellitus is much higher in men with Klinefelter syndrome than in 46,XY men.

Laboratory Findings

Low serum testosterone is common. The karyotype is typically 47,XXY.

Prevention

Screening for cancer, especially of the breast, and for glucose intolerance are indicated.

Treatment

Treatment with testosterone after puberty is advisable but will not restore fertility. However, men with Klinefelter syndrome have had mature sperm aspirated from their testes and injected into oocytes, resulting in fertilization.

After the blastocysts have been implanted into the uterus of a partner, conception has resulted. However, men with Klinefelter syndrome do have an increased risk for aneuploidy in sperm, and therefore chromosome analysis of a blastocyst should be considered before implantation.

Bojesen A et al. The metabolic syndrome is frequent in Klinefelter's syndrome and is associated with abdominal obesity and hypogonadism. Diabetes Care. 2006 Jul;29(7):1591–8. [PMID: 16801584]

Marfan Syndrome

Essentials of Diagnosis

- Disproportionately tall stature, thoracic deformity, and joint laxity or contractures.
- Ectopia lentis and myopia.
- Aortic dilation and dissection.
- Mitral valve prolapse.

General Considerations

Marfan syndrome, a systemic connective tissue disease, has an autosomal dominant pattern of inheritance. It is characterized by abnormalities of the skeletal, ocular, and cardiovascular systems; spontaneous pneumothorax; dural ectasia; and striae atrophicae. Of most concern is disease of the ascending aorta, which begins as a dilated aortic root. Histology of the aorta shows diffuse medial degeneration. Mitral valve leaflets are also abnormal and mitral prolapse and regurgitation may be present, often with elongated chordae tendineae, which on occasion may rupture.

Clinical Findings

Symptoms and Signs

Affected patients are typically tall, with particularly long arms, legs, and digits (arachnodactyly). However, there can be wide variability in the clinical presentation. Commonly, scoliosis and anterior chest deformity, such as pectus excavatum, are found. Ectopia lentis may lead to severe myopia and retinal detachment. Mitral valve prolapse is seen in about 85% of patients. Aortic root dilation is common and leads to aortic regurgitation or dissection with rupture. To diagnose Marfan syndrome, people with an affected relative need features in at least two systems. People with no family history need features in the skeletal system, two other systems, and one of the major criteria of ectopia lentis, dilation of the aortic root, or aortic dissection. Patients with homocystinuria due to cystathionine synthase deficiency also have dislocated lenses; tall, disproportionate stature; and thoracic deformity. They tend to have below normal intelligence, stiff joints, and a predisposition to arterial and venous occlusive disease. Males with Klinefelter syndrome do not show the typical ocular or cardiovascular features of Marfan syndrome and are generally sporadic occurrences in the family.

Laboratory Findings

Mutations in the fibrillin gene (*FBN1*) on chromosome 15 cause Marfan syndrome. Nonetheless, no simple laboratory test is available to support the diagnosis in questionable cases because related conditions may also be due to defects in fibrillin. The nature of the *FBN1* mutation has little predictive value in terms of prognosis. The pathogenesis of Marfan syndrome involves aberrant regulation of transforming growth factor (TGF) activity. Mutations in either of two receptors for TGF (TGFBR1 and TGFBR2) can cause conditions that resemble Marfan syndrome in terms of aortic aneurysm and dissection and autosomal dominant inheritance.

Prevention

There is prenatal and presymptomatic diagnosis for patients in whom the molecular defect in fibrillin has been found and for large enough families in whom linkage analysis using polymorphic markers around *FBN1* can be performed.

Treatment

Children with Marfan syndrome require regular ophthalmologic surveillance to correct visual acuity and thus prevent amblyopia, and annual orthopedic consultation for diagnosis of scoliosis at an early enough stage so that bracing might delay progression. Patients of all ages require echocardiography at least annually to monitor aortic diameter and mitral valve function. All patients should use standard endocarditis prophylaxis. Long-term -adrenergic blockade, titrated to individual tolerance but enough to produce a negative inotropic effect (atenolol, 1–2 mg/kg), retards the rate of aortic dilation. A clinical trial comparing the effectiveness of atenolol and losartan, a drug that reduces activity of TGF- , is underway. Restriction from vigorous physical exertion protects from aortic dissection. Prophylactic replacement of the aortic root with a composite graft when the diameter reaches 45–50 mm in an adult (normal: < 40 mm) prolongs life. A procedure to reimplant the patient's native aortic valve and replace just the aneurysmal sinuses of Valsalva shows promise and also avoids the need for lifelong anticoagulation.

Prognosis

People with Marfan syndrome who are untreated commonly die in the fourth or fifth decade from aortic dissection or congestive heart failure secondary to aortic regurgitation. However, because of earlier diagnosis, lifestyle modifications, beta-adrenergic blockade, and prophylactic aortic surgery, life expectancy has increased by several decades in the past 25 years.

When to Refer

- For detailed ophthalmologic examination.
- For at least annual cardiologic evaluation.
- For moderate scoliosis.
- For pregnancy in a woman with Marfan syndrome.

- For genetic counseling.

When to Admit

Any patient with Marfan syndrome in whom severe or unusual chest pain develops should be hospitalized to exclude pneumothorax and aortic dissection.

Hereditary Hemorrhagic Telangiectasia

Essentials of Diagnosis

- Recurrent epistaxis.
- Mucocutaneous telangiectases.
- Visceral arteriovenous malformations (especially lung, liver, brain, bowel).

Clinical Findings

Symptoms and Signs

Hereditary hemorrhagic telangiectasia (HHT), formerly termed "Osler-Weber-Rendu syndrome, " is an autosomal dominant disorder of development of the vasculature. Epistaxis may begin in childhood or later in adolescence. Punctate telangiectases of the lips, tongue, fingers, and skin generally appear in later childhood and adolescence. Arteriovenous malformations (AVMs) can occur at any age in the brain, lungs, and liver. Bleeding from the gastrointestinal tract is due to mucosal vascular malformations and usually is not a problem until mid-adult years or later. Pulmonary AVMs can cause hypoxemia (with peripheral cyanosis, dyspnea, and clubbing) and right-to-left shunting (with embolic stroke or brain abscess). The criteria for diagnosis require presence of three of the following four features: (1) recurrent epistaxis, (2) visceral AVMs, (3) mucocutaneous telangiectases, and (4) being the near relative of a clearly affected individual. Mutation analysis can be used for presymptomatic diagnosis or exclusion of the worry of HHT.

Laboratory Findings

MR or CT arteriography detects AVMs. Mutations in at least five genes can cause HHT. Three have been identified and molecular analysis to identify them is available; these mutations in *ENG*, *ALK1* and *SMAD4* account for about 70% of families with HHT.

Prevention

Embolization of pulmonary AVMs reduces the risk of stroke and brain abscess. Treatment of brain AVMs reduces the risk of hemorrhagic stroke. All patients with HHT should practice routine endocarditis prophylaxis. All intravenous lines should have an air-filter to prevent embolization of an air bubble. Prenatal diagnosis through mutation detection is possible.

Treatment

All patients in whom the diagnosis of HHT is considered should have an MRI of the brain with contrast. A contrast echocardiogram will detect most pulmonary AVMs when "bubbles" appear on the left side of the heart after 3–6 cardiac cycles. A positive contrast echocardiogram should be followed by a high-resolution CT angiogram for localization of pulmonary AVMs. Patients who have AVMs with a feeding artery of 1 mm diameter or greater should undergo embolization. After successful embolization of all treatable pulmonary AVMs, the CT angiogram should be repeated in 3 years. A person with a negative contrast echocardiogram should have the test repeated every 5 years.

Information Technology in Patient Care: Introduction

After many decades of trailing other sectors of the economy, health care and health professional education have embraced information technology as a strategic resource in the last decade. Computers and the Internet have become standard means for performing other information-intensive, high-consequence activities. Much of the population now use computers for planning travel, banking, bill payment, and correspondence. Increasingly and reasonably, patients and health care professionals expect a comparable level of technological sophistication and online customer service from the health care system.

The scope of information a clinician must produce, assimilate, synthesize, record, and communicate in modern health care systems exceeds the capacity of information systems based on the movement of paper. Information technology has tremendous potential in health care that is only beginning to be actualized. The technical and theoretical details underlying clinical informatics are beyond the scope of this chapter. What follows is a concise introduction to topics and resources of general interest in this field, presented to help clinicians use information technology for the benefit of patient care.

Clinical Uses of E-Mail

Electronic communication can extend and complement direct patient encounters, improve adherence and access to care, and increase the involvement of patients in their own care. E-mail is well-suited for communicating administrative information, medication or dressing instructions, patient education materials, routine laboratory results, appointment reminders, and prescription refills. It can augment home monitoring of treatment plans, such as diabetic diets or smoking cessation programs. Providers can make general announcements to an entire patient practice about issues such as vacation coverage, influenza vaccine availability, changes in referral procedures, or withdrawal of medications from the market (Table e4–1).

Table e4–1. Some suggested uses of patient-provider e-mail.
Patient education
Medication, diet, or dressing instructions
Multimedia disease education presentations
References to appropriate Internet resources
Disease monitoring
Home glucose, blood pressure, weight, or peak flow measurements
Progress toward smoking cessation
Administrative information
Referral requests
Vacation coverage
Changes in demographic data
Patient requests for prescription refills
Normal laboratory test results and interpretation
Reminders
Scheduled appointments
Vaccines or screening tests due
Clarifications, follow-ups, or reinforcement of issues discussed in person

However, the nature of e-mail creates legal, ethical, and practical considerations that must be considered by patients and health care professionals. E-mail is more permanent than oral communication and more spontaneous than paper correspondence and other written communications. It is by its nature self-documenting. E-mail can be duplicated or forwarded with a few keystrokes and little thought, and copies may linger on intermediate or back-up computer systems long after the sender and receiver have deleted the originals. The casual and conversational nature of e-mail in the absence of nonverbal social cues commonly leads to misunderstandings. E-mail can be easily altered by the sender, the recipient, or a third party, retrospectively and without attribution. It is very difficult to positively identify the sender or recipient on the other end of an e-mail address, and with modest technical expertise it is easy to fabricate an e-mail from most addresses.

The security and privacy rules of the Health Insurance Portability and Accountability Act (HIPAA) place important requirements on the "covered entity" (the individual physician or group) to ensure the security of protected health information as it is transmitted and stored. E-mail transmitted over the Internet by many commercial providers is entirely insecure, and interception of that e-mail by a malicious party is easy to accomplish. Clinicians often incorrectly assume if an e-mail exchange containing protected health information was initiated by the patient, the patient has "consented" to this form of insecure information exchange. However, HIPAA contains no provisions for "consenting" to communications that violate its security rule, and patients have no power to relieve clinicians of their obligations under this federal regulation. In addition, HIPAA requires not only the secure transmission of protected health information but also its secure storage. E-mails stored on a computer, especially a laptop, are vulnerable to theft either physically or remotely over networks. Although case law is only beginning to be developed in this area, the potential penalties are significant, and widely reported serious incidents of electronic theft of other types of sensitive information highlight the risks. Furthermore, some jurisdictions (prominently, the Veterans' Health Administration and the State of California) have imposed stricter requirements and higher fines than provided in Federal law.

Clinicians can take several steps to minimize these risks. First, clinicians must never use poorly secured, unencrypted e-mail to exchange protected health information, even if the exchange was initiated by a patient. Numerous commercial services for secure, private exchange of clinical e-mail with patients aimed at health-care providers are available in the marketplace. Secondly, any clinical information stored electronically outside of an enterprise clinical system, such as on an individual computer or laptop, must be both electronically and physically secure. Electronic security includes the correct use of strong passwords or other strong authentication methods, network firewalls, virus protection, spyware protection, and data encryption. The security inherent to most consumer-oriented computer hardware and operating systems is not sufficient, and proper security requires technical sophistication or professional expertise. Physical security includes barring direct access to such computers by unauthorized individuals. Laptop computers represent a special risk in this regard, and the theft or misplacement of a laptop containing clinical information, even if only in the form of incidental e-mails, can have far-reaching legal and financial consequences for an individual clinician and the clinician's employer. Some newer laptops have the ability for the entire hard drive to be physically encrypted and require biometric authentication, such as a fingerprint, to gain access, and may offer valuable risk mitigation if laptops are used for clinical purposes.

Lastly, wireless networks in the home and public areas are ubiquitous. Many of these are entirely insecure, and malicious interception of wireless network traffic is technologically simple and well described. Clinicians should never conduct clinical work involving protected health information using publicly accessible wireless networks, such as in airports or coffee shops, without an additional layer of network security such as a virtual private network (VPN), and must take steps to appropriately secure a home wireless network.

Clinicians are sometimes concerned that once their e-mail addresses become widely available, they will be deluged by messages from individuals with whom they have no preexisting relationship. Studies have not found the volume of e-mail from unfamiliar patients to be burdensome in practice. However, there is currently no consensus on the physician's duty in this situation. Additionally, there may be legal consequences to providing advice to patients who are out of state or abroad and thus beyond the scope of the physician's license. At minimum, physicians should post electronic communication policies addressing unsolicited communication wherever their e-mail addresses can be found.

Electronic Medical Records

Electronic medical records continue to enjoy a high level of public national interest. In three consecutive State of the Union Addresses, President George W. Bush cited electronic health records for every American as a national goal. In the 2008 presidential election, candidates widely agreed on the importance of increased electronic medical records adoption, and in his campaign President Obama proposed spending $50 billion over 5 years on health information systems adoption. The interest stems from the potential of electronic medical records to provide large-scale improvements in the efficiency, safety, and cost-effectiveness of health care. A widely cited RAND study estimated $77 billion in annual cost savings in the United States if electronic medical records were widely adopted. Once a niche market dominated by specialty software vendors, electronic medical records are now a field of intense commercial competition with entries by large multinational software vendors. Mature products are available catering to the needs of individual physicians, group practices, and large integrated delivery networks. Offerings range from general solutions hoping to please all practitioners to highly targeted solutions for subspecialists.

Providers and health systems often focus heavily on the selection of appropriate software when contemplating conversion to an electronic medical record. Although good software is critical, the challenge of conversion to an electronic medical record is seldom primarily one of technical implementation, but rather the challenges of process redesign, understanding and supporting workflows, and economic and social aspects of organizational change. To assist purchasers in selecting clinical software meeting a baseline set of functional requirements, industry groups have created the Certification Commission for Healthcare Information Technology (CCHIT) to certify products with a baseline feature set. The first certifications were awarded to ambulatory clinical software in July 2006 and most recently updated in November 2008, and the first certifications for inpatient software were awarded in November 2007. The challenge of workflow analysis and organizational change is a topic of ongoing industry and research interest and is necessarily local to each care setting. Many consulting firms specialize in health care information technology transformation, or have health care IT practices to provide assistance. The Joint Commission (formerly the Joint Commission on the Accreditation of Healthcare Organization, JCAHO) has issued a Sentinel Event Alert, in which these challenges are discussed and general implementation guidelines are offered. The emerging role of Chief Medical Information Officer and similar roles at many hospitals recognizes the need for leadership that spans the clinical enterprise, as Information Technology departments now find themselves counted among the clinical services, alongside

Radiology and Laboratory departments. Increasingly, the software vendors are recognizing the value of providing standards for leadership in organizational change as a package with their software products, and some of the currently most successful clinical software vendors distinguish themselves in part through these services.

To date, commercially available systems offer limited interoperability with one another. Although messaging standards exist for communicating structured data elements among systems, to date an electronic medical record implemented in one hospital or clinic remains confined within the network of that system. The large-scale estimates of gains in efficiency and productivity in health care are predicated on the development of regional or national interoperability between health care information systems. Although work is under way to describe and standardize such interoperability, notably promoted by the Office of the National Coordinator for Health Information Technology, progress remains slow and uneven and the goal seems unlikely to be broadly achieved in the United States within the next several years.

Computerized Provider Order Entry

Of the many components that make up a clinical information system, perhaps the greatest promise has been ascribed to computerized provider order entry. Enthusiasm stems from the potential safety and quality benefits of eliminating problems with legibility, ambiguous abbreviations, and delays in order communication, and from the clinical benefits of automated dose checking, drug-drug interaction checking, drug-allergy checking, guideline promotion and standardization of care, and other more sophisticated forms of real-time clinical decision support. The evidence for the benefit of computerized provider order entry is considered solid, in addition to the face value improvement of order quality, completeness, and communication speed. The Leapfrog Group, an influential cooperative of health-care payers, has made adoption of computerized provider order entry a central feature of their pay-for-performance initiatives, and in 2002, California mandated in statute a "technology implementation, such as, but not limited to, computerized provider order entry . . . to eliminate or substantially reduce medication related errors in the facility" for all hospitals in the state.

Computerized provider order entry systems have enjoyed many well-documented successes, and although a relatively small percentage of hospitals have installed them, many are planning installations. The installation and adoption of a computerized provider order entry system is a substantial challenge, and there have been a handful of spectacular failures. As with electronic medical record systems, the failure is seldom one of technology, but rather of accurate and complete support of clinician workflow, attention to system usability, social and organizational factors, and adequate training and support. Furthermore, there have been a handful of high-profile reports of degradation in patient safety indicators subsequent to the installation of computerized provider order entry systems. These reports underscore that a transformational change in the process of care delivery necessarily contains hazards. The fact that computerized provider order entry has demonstrated benefits across many settings is not a guarantee that it will be beneficial in all implementations in all places. Software systems that account for the workflow and usability challenges and vendors that provide customers with not only software but outstanding implementation guidance and support will thrive in this competitive marketplace.

Clinical Decision Support Systems

In contrast to general clinical information sources, such as continuously updated online journals and medical references, computerized clinical decision support systems directly assist the clinician in making decisions about a specific patient. Decision support systems do not need to be sophisticated to have a significant impact. For example, simple dose-range checking for medications (such as opiates and insulin), drug-drug interaction checking, and drug-allergy checking are conceptually straightforward but can catch a critical source of human error that no amount of personal vigilance will entirely eliminate. Slightly more advanced are systems that analyze clinical data (such as calculating a creatinine clearance) and present guidance based on those data. More sophisticated examples are systems that look for trends in values, such as the rate of fall of the hematocrit or the rising weight of an ICU patient who is accumulating extracellular fluid, where an absolute number may not be noted by the decision support system or clinician, but an alert to the trend may be important and prompt action.

Although simple to describe, decision support systems are challenging to implement and maintain. The most vexing problem is the workflow and human-computer interaction challenge of "alert fatigue." Studies within and outside health care show that the beneficial effect of an alert, such as a pop-up box in a software system, is rapidly extinguished if the alert becomes a routine part of using the system. A familiar example of alert fatigue is the casual attention given to the audible low-level alerts produced by cardiac telemetry systems. If a clinical decision support system provides an "alert" to the drug-drug interaction of two medications routinely used together safely, such as enoxaparin and warfarin, in the same way as to the unfamiliar but dangerous interactions that would be useful to highlight, such as theophylline and fluoroquinolones, clinicians become desensitized to the alerts and dismiss critically important guidance when it does appear. The best clinical systems offer fine-grained tuning of the system's behavior, such as setting the system's response by drug and provider specialty, and offer a range of interruptive and noninterruptive support mechanisms. However, even these measures have yet to demonstrate consistent improvement in the effectiveness of alerts. The price of this flexibility is the effort in design and maintenance on the part of the implementing institution.

The most complex decision support systems attempt to aid in making a clinical diagnosis. The application of artificial intelligence to medicine has a long history; however, most such systems have been stand-alone, requiring effort by the clinician outside of their normal workflow, and have thus seen limited clinical implementation. Examples of clinical diagnostic systems directly imbedded in an electronic medical record are few, but are an area of increasing commercial interest (Table e4–2).

Table e4–2. Functional classes and examples of clinical decision support systems.

Class	**Function**	**Examples**
Feedback	Provide feedback by responding to an action taken by the clinician or to new data entered into the system	Drug family checking results in alerts on allergies, drug-drug interactions, and other patient-specific conflicts. Parameter checking looks for dosing errors and other parameter discrepancies in patient-specific scenarios (eg, gentamicin dosing

		in advanced chronic kidney disease). Redundant utilization checking alerts physicians to duplicate test orders.
Data organization	Organization and presentation of disparate data into logical, intuitive schemas at the point-of-need	Aggregate data trending observes key indicators for large numbers of patients over time (eg, emergence of antibiotic resistance patterns).
Proactive information	Provision of information to the clinician at the point-of-need (eg, clinical pathway on pneumonia when patient with pneumonia is being	Template and order sets can be provided to given situations.

	admitted to hospital)	
Intelligent actions	Automation of routine and repeated tasks for the clinician on a regular time schedule (eg, provision of all new laboratory values on current patient list every morning)	Rule-based event detection allows users to create logical rules to be checked when triggering events occur (eg, check glucose level in hyponatremia). Time-based checks to post reminders when expected transactions have not occurred (eg, warfarin order not filled by 8:00 pm).
Communication	Alert clinician and other providers who need to know about unusual data (eg, test results) or communications regarding specific patients	Parameter alerts provide clinicians with key information on panic values. Automated e-mails send information to clinicians when

		provider-patient encounters occur (eg, e-mail to primary doctor when patient is evaluated in the emergency department).
Expert advice	Diagnostic and therapeutic advice using a comprehensive knowledge base and a problem-solving method, such as probabilistic reasoning, neural nets, or heuristic rules	Differential diagnosis and suggestions for further testing generated from patient-specific data. Reducing uncertainty in test interpretation (eg, probability of pulmonary embolism given patient demographics and indeterminate ventilation-perfusion scan).

Web Sites & Online Health-Related Forums

An individual clinician's Internet use depends on his or her interests and personal requirements. Many clinicians, either individually or through their practice group, maintain a Web site for their practice as a service to their patients. For the individual practitioner or small group, very affordable Web authoring and hosting services are available commercially. Large groups and institutions typically maintain their own Web sites, and assist the individual provider in representing themselves in a standardized way. Offering clinical information to patients or communicating patient-related health information over the Internet requires consideration of legal issues. Providing medical content can be construed as formal medical advice. General patient education material and online recommendations should be followed by instructions directing patients to first discuss any suggested lifestyle or medication changes with a physician before adoption.

Many clinicians increasingly turn to online resources for references and to obtain continuing medical education. Numerous high-quality medical news Web sites are available, and most medical journals offer direct access to current and archived issues to individual subscribers and institutions. Web sites specifically aimed at clinicians provide a constantly expanding repository of information previously inaccessible to most clinicians and their patients. Continuing concerns with some Web sites offering health-related information include that they may lack the accuracy, timeliness, and reliability of carefully curated sources, offline or online. Several Web sites have established a favorable brand reputation. Review services provide rating criteria as well as seals of approval that individual Web sites can apply for and display to indicate compliance with established codes of conduct. A leading example is the Geneva-based Health on the Net Foundation. Table e4–3 is an example of a well-constructed rating system.

Table e4–3. An example of a well-constructed rating system.

Peer reviewed	Web page claims that other experts in the field have critically evaluated material presented.

Updated regularly	Content was updated within 6 months of researching this guide.

Informal consultations among clinicians are common, but historically have been limited to the offices and conference rooms within a health care setting or at periodic academic meetings. The Internet and its dramatic reduction in barriers to communication have made these activities continuous and far-reaching.

Many online discussion groups are available for health care providers with similar interests (Table e4–4). Almost all function as electronic bulletin boards, where individuals leave new messages or comments relevant to ongoing discussion threads (topics). A prominent example is Patients Like Me, http://www.patientslikeme.com/, which provides forums for a variety of chronic diseases.

Table e4–4. Examples of interactive forums.

Program for Monitoring Emerging Diseases (PROMED) (http://www.promedmail.org)
Medical Matrix Internet Medical Resource Mailing List (http://listserv.acor.org/archives/mmatrix-l.html)

Newsgroups are one of the oldest applications of the

Internet, predating the World Wide Web, although today the Web provides a convenient interface. There are tens of thousands of newsgroups open to the general public, though they are usually unmoderated and are subject to little or no information quality control. There are many ways to access newsgroups; among the easiest is to browse through them at http://groups.google.com.

Other forums include discussion areas attached to a specific Web site. Some require registration demonstrating credentials (eg, medical license number), and moderators may monitor postings for accuracy and relevance. Web-based forums generally carry discussions of higher quality among fewer participants.

Mailing lists are discussions delivered directly by e-mail. Any comment posted to the ongoing dialogue is sent to every subscriber. Mailing lists can be moderated or unmoderated, private or public, and may have as few as two or as many as tens of thousands of subscribers. High-volume lists can produce hundreds of postings each day and can be received in a digest mode, which gathers the postings into a single periodic e-mail message.

The Internet's closest approximation to a face-to-face conversation takes place in chatrooms, where participants type text live and it is visible to the whole group as the discussion unfolds. Although—as with everywhere on the Internet—it is impossible to conclusively verify the identities of those with whom one is communicating, quality chatrooms provide moderators, discussants, or attendants responsible for guiding discussions and removing disruptive participants. Most chatrooms of interest to health care providers are hosted by medical Web sites.

Instant messaging applications allow real-time, synchronous text chat and file exchange with other online users such as patients and other clinicians. Clinicians should remember that although instant messaging provides the appearance of a private discussion, these systems are not secure and do not provide suitable privacy for discussion of confidential information.

Mobile Computing for Clinicians

A remarkable variety of mobile computing devices are available, ranging from "smart" cell phones to small hand-help personal computers to tablet personal computers and lightweight laptops. Every month sees the release of a smaller, faster, or cheaper device in this competitive market.

Among the most widely used devices are personal digital assistants (PDAs), often combining a cellular telephone. The defining features of PDAs include their pocket size and their "instant on" capability without the startup time usual with devices running a full-fledged operating system. PDAs are designed for limited data input, although devices for e-mail and other interactive communications with thumb keyboards have achieved significant market penetration. Common activities on the limited screen size include reference applications designed for the form such as electronic pharmacopoeia, and applications for charge capture, limited note-taking, and e-mail composition. Lightweight forms of decision support, such as medical calculators, opiate dose-equivalent converters, and drug-drug interaction checkers are widely used. Large data entry tasks such as clinical documentation or full scale order-writing is not realistic on these devices. Enterprising clinical information systems vendors are increasingly offering stripped-down user interfaces for small devices, and several bolt-on applications are available.

Telemedicine

Telemedicine can be defined as "the use of information and communications technologies to provide and support health care when distance separates the participants." Clinicians have been practicing telemedicine via the telephone since the telephone was invented. The first video telemedicine application was tested in the 1960s by neurologists and psychiatrists in Nebraska.

Telemedicine applications of the past 20 years have focused on interactive video to connect patients and referring clinicians in remote locations with specialists in urban tertiary care centers. Visual and audio information was at first conveyed by physical transportation of recording media but now is streamed over secured channels on the Internet.

The next generation of telemedicine applications may expand the remote clinician's capabilities beyond diagnosis to therapeutic interventions. Telesurgery, remote psychotherapy, and virtual home visits to manage chronic medical problems have all been demonstrated, although deployment remains limited. Remote monitoring of chronic medical conditions using networked medical devices such as blood pressure cuffs or blood glucose monitors has become increasingly popular. Multiple Web sites describe these and other innovative uses of telemedicine for interested clinicians to explore (Table e4–5).

Table e4–5. Examples of current telemedicine applications.
In-flight emergency resuscitation guidance on commercial aircraft
Home fetal monitoring during complicated pregnancies
Monitoring compliance with home drug dispensers
Preoperative screening and postoperative follow-up of patients of surgeons on service missions to developing nations
Remote dermatologic, pathologic, or radiographic consultations
Teleproctoring laparoscopic surgery
Providing specialty care to incarcerated violent criminals
Directly observed therapy (DOT) for tuberculosis
Remote monitoring of ICU patients by intensivists

Although information transfer ignores geographic boundaries, medical licensure does not—especially in the United States, where several states have explicitly limited the interstate practice of telemedicine. Liability and malpractice are thorny issues, as the practice of telemedicine presents a new form of the patient-caregiver relationship and associated hazards, such as technical failures leading to altered or suboptimal data.

Health care payer policy is lagging behind the technology. Medicare and other insurers will reimburse telemedicine visits that meet a restrictive set of criteria. Consultative teleradiology is usually reimbursed, as are certain consultations, office visits, individual psychotherapy, and pharmacologic management sessions when they involve interactive audio and video. Triage, diagnosis, and advice are rarely covered by video, just as they are largely excluded from coverage when performed by telephone.

Therapeutic Drug Monitoring & Laboratory Reference Intervals

See Table 1, Therapeutic Drug Monitoring, Table 2, Reference Intevals for Commonly Used Tests, and Table 3, Commonly Used Specimen Collection Tubes.

Table 1. Therapeutic drug monitoring.[1]

Drug	Effective Concentrations	Half-Life (hours)	Dosage Adjustment	Comments
Amikacin	Peak: 20–30 mg/L; trough: < 10 mg/L	2–3; in uremia	in renal dysfunction	Concomitant kanamycin or tobramycin therapy may give falsely elevated amikacin results by immunoassay.
Amitriptyline	95–250 ng/mL	9–46		Drug is highly protein-bound. Patient-specific decrease in protein binding may invalidate quoted therapeutic

				reference interval for effective concentration.
Carbamazepine	4–12 mg/L	10–15		Induces its own metabolism.
				Metabolite 10,11-epoxide exhibits 13% cross-reactivity by immunoassay. Toxicity: diplopia, drowsiness, nausea, vomiting, and ataxia.
Cyclosporine	100–300 mcg/L (ng/mL) whole blood	6–12	Need to know specimen and methodology used	Cyclosporine is lipid-soluble (20% bound to leukocytes; 40% to erythrocytes; 40% in

				plasma, highly bound to lipoproteins); the binding is temperature-dependent in vitro and concentration-dependent in vivo. Obtain whole blood sample in a lavender (EDTA) tube for monitoring. HPLC and LC-tandem mass spectrometry methods are highly specific for parent drug and considered as

				the gold standard assays. Monoclonal fluorescence polarization immunoassay (FPIA) also measures cyclosporine reliably; polyclonal FPIAs are less specific due to cross-reaction with drug metabolites. Anticonvulsants and rifampin increase metabolism. Erythromycin, ketoconazole, and calcium

				channel blockers decrease metabolism. The main adverse reaction is dose-related nephrotoxicity.
Desipramine	100–250 ng/mL	13–23		Drug is highly protein-bound. Patient-specific decrease in protein binding may invalidate quoted therapeutic reference interval for effective concentration.
Digoxin	0.8–2	42: in	in	Bioavailabilit

	ng/mL	uremia, CHF	renal dysfunction, CHF, hypothyroidism in hyperthyroidism	y of digoxin tablets is 50–90%.
				Specimen must not be drawn within 6 hours of dose.
				Dialysis does not remove a significant amount.
				Hypokalemia potentiates toxicity.
				Digitalis toxicity is a clinical and *not* a laboratory diagnosis.
				Digibind (digoxin-specific antibody) therapy of

				digoxin overdose can interfere with measurement of digoxin levels depending on the digoxin assay.
				Elimination reduced by quinidine, verapamil, and amiodarone.
Ethosuximide	40–100 mg/L	Child: 30		Levels used primarily to assess compliance. Toxicity is rare and does not correlate well with plasma concentrations.
		Adult: 50		
Gentami	Peak: 4–8	2–5: in	in	Draw peak

cin	mg/L; trough: < 2 mg/L	uremia (7.3 on dialysis)	renal dysfunction	specimen 30 minutes after end of infusion.
				Draw trough just before next dose.
				In uremic patients, carbenicillin may decrease gentamicin half-life from 46 hours to 22 hours.
Imipramine	180–350 ng/mL	10–16		Drug is highly protein-bound. Patient-specific decrease in protein binding may invalidate quoted therapeutic

				reference interval for effective concentration.
Lidocaine	1–5 mg/L	1.8 in uremia, CHF; in cirrhosis	in CHF, liver disease	Levels increased with cimetidine therapy.
				CNS toxicity common in the elderly.
Lithium	0.7–1.5 mmol/L	22; in uremia	in renal dysfunction	Thiazides and loop diuretics may increase serum lithium levels.
Methotrexate		8.4; in uremia	in renal dysfunction	Therapeutic concentrations depend on the treatment protocol (low versus high dose) and time of specimen collection.

				7-Hydroxymethotrexate cross-reacts 1.5% in immunoassay.
				To minimize toxicity, leucovorin should be continued if methotrexate level is > 0.1 mcmol/L at 48 hours after start of therapy. Methotrexate > 1 mcmol/L at > 48 hours requires an increase in leucovorin rescue therapy.
Nortriptyline	50–140 ng/mL	18–44		Drug is highly

				protein-bound. Patient-specific decrease in protein binding may invalidate quoted therapeutic reference interval for effective concentration.
Phenobarbital	10–40 mg/L	86; in cirrhosis	in liver disease	Metabolized primarily by the hepatic microsomal enzyme system.
				Many drug-drug interactions.
Phenytoin	10–20 mg/L; 5–10 mg/L in uremia,	Dose/concentration-dependent		Drug metabolite cross-reacts in immunoassay

	hypoalbuminemia			s; the cross-reactivity may be of significance only in the presence of advanced chronic kidney disease.
				Metabolism is capacity-limited. Increase dose cautiously when level approaches therapeutic reference interval, since new steady-state level may be disproportionately higher.
				Drug is very highly

				protein-bound; protein binding is decreased in uremia and hypoalbuminemia. Free drug level may be indicated in certain circumstances.
Primidone	5–10 mg/L	8		Phenobarbital cross-reacts 0.5%.
				Metabolized to phenobarbital.
				Primidone/phenobarbital ratio > 1:2 suggests poor compliance.
Procainamide	4–8 mg/L	3; in	in	30% of patients with

		uremia	renal dysfunction	plasma levels of 12–16 mcg/mL have ECG changes; 40% of patients with plasma levels of > 16 mcg/mL have severe toxicity. Metabolite *N*-acetylprocainamide is active.
Quinidine	1–4 mg/L	7 x in CHF; in liver disease	in liver disease, CHF	Effective concentration is lower in chronic liver disease and nephrosis, where binding is decreased.
Salicylate	150–300 mg/L	Dose-dependent		
Sirolimus	Trough: 4–12	62	in	Sirolimus is an

	ng/mL when used in combination with cyclosporine A; 12–20 ng/mL if used alone.		liver dysfunction and with drugs affecting CYP3A4 activity	immunosuppressant used in combination with cyclosporine and corticosteroids for prophylaxis of organ rejection after kidney transplantation. It has also been used in liver and heart transplantation. When used in combination with cyclosporine, careful monitoring of kidney function is required.

				Once the initial dose titration is complete, monitoring sirolimus trough concentrations weekly for the first month and every 2 weeks for the second month appears to be appropriate.
Tacrolimus	Trough: 5–20 ng/mL	8.7–11.3	in liver dysfunction and with drugs affecting CYP3A4 activity	Tacrolimus is used for prophylaxis of organ rejection in adult patients undergoing liver or kidney transplantation and in

				pediatric patients undergoing liver transplantation. It has also been used to prevent rejection in heart, small bowel, and allogeneic bone marrow transplant patients and to treat autoimmune diseases.
				Antacid or sucralfate administration should be separated from tacrolimus by at least 2 hr.
Theophy	5–20	9	in	Caffeine

lline	mg/L		CHF, cirrhosis, and with cimetidine	cross-reacts 10%. Elimination is increased 1.5–2 times in smokers. 1,3-Dimethyl uric acid metabolite increased in uremia and, because of cross-reactivity, may cause an apparent slight increase in serum theophylline.
Tobramycin	Peak: 5–10 mg/L; trough: < 2 mg/L	2–3; in uremia	in renal dysfunction	Tobramycin, kanamycin, and amikacin may cross-react in immunoassay.
Valproic acid	55–100 mg/L	13–19		95% protein-bound.

				Decreased binding in uremia and cirrhosis.
Vancomycin	Trough: 5–15 mg/L	6; in uremia	in renal dysfunction	Toxicity in uremic patients leads to irreversible deafness. Keep peak level < 30–40 mg/L to avoid toxicity.

[1] Use red-topped tube (not marbled) for therapeutic drug monitoring. In general, the specimen should be drawn just before the next dose (trough).

, unchanged; , increase(d); , decrease(d); HPLC, high performance liquid chromatography; CHF, congestive heart failure; CNS, central nervous system; ECG, electrocardiogram.

Modified, with permission, from Nicoll D et al. *Pocket Guide to Diagnostic Tests*, 5th ed. McGraw-Hill, 2008.

Table 2. Reference intervals for commonly used tests.[1,2]

Current metric units x Conversion factor = SI units **SI units ÷ Conversion factor = Current metric units**					
Test	**Specimen**	**Conventional Units**	**Conversion Factor**	**SI Units^2**	**Collection**
Acetaminophen	Serum	10–20 mg/L **Panic:** > 50 mg/L	66.16	66–132 mcmol/L	Serum separator tube (SST)
Acetoacetate	Serum or urine	Negative		Negative	SST or urine container
Activated clotting time (ACT)	Whole blood	70–180 seconds (method-specific)			Collect in a plastic syringe without anticoagulant

Adrenocorticotropic hormone (ACTH)	Plasma	9–52 pg/mL (laboratory-specific)	0.22	2–11 pmol/L	Siliconized glass or plastic lavender
Alanine aminotransferase (ALT, SGPT, GPT)	Serum	7–56 units/L (laboratory-specific)	0.02	0.14–1.12 mckat/L (laboratory-specific)	SST
Albumin	Serum	3.4–4.7 mg/dL	10.00	34–47 g/L	SST
Aldosterone	Serum	Salt-loaded (120 mEq Na$^+$/d for 3–4 days):	27.74		SST
		Supine: 3–10 ng/dL		83–277 pmol/L	

		Upright: 5–30 ng/dL		139–831 pmol/L	
		Salt-depleted (20 mEq Na$^+$/d for 3–4 days):			
		Supine: 12–36 ng/dL		332–997 pmol/L	
		Upright: 17–137 ng/dL		471–3795 pmol/L	
	Urine	Salt-loaded (120 mEq Na$^+$/d for 3–4 days): 1.5–12.5 mcg/24 h	2.77	4.2–34.6 nmol/d	Urine bottle containing boric acid
		Salt-depleted (20 mEq		49.9–235.5	

		Na$^+$/d for 3–4 days): 18–85 mcg/24 h		nmol/d	
Alkaline phosphatase	Serum	41–133 units/L (method- and age-dependent)	0.02	0.7–2.2 mckat/L (method- and age-dependent)	SST
Ammonia (NH$_3$)	Plasma	18–60 mcg/dL	0.59	11–35 mcmol/L	Green (iced)
Amylase	Serum	20–110 units/L (laboratory-specific)	0.02	0.33–1.83 mckat/L (laboratory-specific)	SST

Table 3. Commonly used specimen collection tubes.

Tube	**Tube Contents**	**Typical Use**
Lavender	EDTA	Complete blood count; molecular testing
SST	Serum separator	Serum chemistry tests
Red	None	Blood banking (serum); therapeutic drug monitoring
Blue	Citrate	Coagulation studies
Gray	Inhibitor of glycolysis (sodium fluoride)	Lactic acid
Green	Heparin	Plasma chemistry tests; chromosome analysis
Yellow	Acid citrate	HLA typing; flow cytometry immunophenotyping
Navy	Trace metal free	Trace metals (eg, lead, mercury, arsenic)

EDTA, ethylenediamine tetraacetic acid; SST, serum separator tube.

Complementary & Alternative Medicine: Introduction

The use of complementary and alternative medicine (CAM) has become common in the United States. To maintain effective clinician-patient communication and ensure responsible clinical practice, it is important that clinicians learn the theory, practice, and scientific evidence associated with these therapies. This chapter provides an overview of four alternative medicine therapies: herbal medicine, nonherbal dietary supplements, acupuncture, and mind-body medicine.

General Considerations

CAM is defined by the National Institutes of Health (NIH) as a group of diverse health care systems, practices, and products that are not presently considered to be part of conventional medicine. CAM therapies may be used alone as an alternative to conventional therapies or in addition to conventional, mainstream medicine to treat conditions and promote well being.

CAM modalities have been classified by NIH into five major categories:

Biologically based practices use substances found in nature, such as herbs, special diets, or vitamins (in doses outside those used in conventional medicine).

Energy medicine involves the use of energy fields, such as magnetic fields or biofields (energy fields that some believe surround and penetrate the human body). Examples include Reiki, external qigong, and therapeutic touch.

Manipulative and body-based practices use manipulation or movement of one or more body parts (massage, chiropractic, Feldenkrais method and other "body work" systems).

Mind-body medicine uses a variety of techniques designed to enhance the mind's ability to affect bodily function and symptoms, such as biofeedback, meditation, prayer, art and music therapy, hypnosis, and guided imagery.

Whole medical systems are built on complete systems of theory and practice that have evolved apart from—and often earlier than—the conventional medical approach used in the United States. Systems such as traditional Oriental medicine, acupuncture, homeopathy, naturopathy, Ayurveda, and Tibetan medicine often use one or more of the methods listed above.

The Centers for Disease Control and Prevention conducted National Health Interview Surveys (NHIS) in 2002 and 2007. Overall, 23,300 American adults from diverse populations were asked about their use of CAM in the 2007 survey. Thirty-eight percent reported using some form of CAM in the previous 12 months, essentially unchanged from 36% in 2002. The most commonly used CAM therapies were nonvitamin, nonmineral natural products (17.7%), with fish oil, glucosamine, echinacea, flaxseed and ginseng being the most common; deep breathing exercises (12.7%); meditation (9.4%); chiropractic or osteopathic manipulation (8.6%); massage (8.3%); and yoga (6.1%). CAM use was higher among women, adults aged 30–69 years, those with higher levels of education, who were not poor, who live in the West and who have quit cigarette smoking. The most common conditions for which adults used CAM were similar to those seen in most primary care offices: musculoskeletal complaints, such as back, neck, and joint pain. Similar to 2002, CAM usage in 2007 was positively associated with the number of health conditions and number of doctor visits in the past 12 months. Most people who use CAM combine it with conventional medicine because they perceive the combination to be superior to either alone.

Dissatisfaction with conventional medicine has not previously been found to predict greater CAM use, but more than 25% of US adults in the 2002 survey said they used CAM because they believed conventional medicine could not help them. No questions on health care spending were asked during NHIS interviews, but a smaller national phone survey conducted in 1997 estimated that the US public paid $36 billion on CAM therapies, much of it out-of-pocket.

In January 2005, the Institute of Medicine of the National Academies released a report on the use of CAM in the United States. They recommended "health profession schools incorporate sufficient information about complementary and alternative medicine (CAM) into the standard curriculum at all levels to enable licensed professionals to competently advise their patients about CAM." Indeed, despite the growing numbers of patients seeking CAM, less than 40% of alternative therapies used are disclosed to physicians. In one survey of 1559 patients age 50 or older, 70% who used CAM did not tell their physician. A lack of communication may be dangerous because some CAM therapies can interact adversely with conventional treatments.

Funding for biomedical research in this field increased when the NIH established the Office of Alternative Medicine in 1992 with an annual budget of $2 million. In

1998, its role was expanded as the National Center for Complementary and Alternative Medicine (NCCAM). NCCAM's budget for fiscal year 2008 was $122 million. Although some CAM modalities are not easily evaluated using randomized control trial methodology, the 2005 Institute of Medicine report recommends that conventional and CAM treatments both be held to similar standards of safety and efficacy.

Herbal Medicines

Epidemiology

For thousands of years, plants have been used worldwide for medicinal purposes, dispensed by traditional herbalists who have been involved with their cultivation and preparation as well as assessment of their potency. At present, most herbal products are commercially cultivated, processed in unregulated environments, and purchased over-the-counter without the counseling of a qualified health practitioner.

The use of herbs in the United States has increased dramatically over the past decade, although sales have leveled off over the past several years. Herbal products are used by one of five Americans at an annual total cost of more than $4 billion, but fewer than half of those individuals discuss the matter with a conventional health care provider. Consumers hold strong views about the efficacy of the supplements they take. Seventy percent state that they would continue to take their favorite supplement even if a government study claimed it was not effective.

Regulatory Issues

In 1994, the United States Congress unanimously passed the Dietary Supplement and Health Education Act. This legislative act classifies vitamins, minerals, herbs, and amino acids as nutritional or dietary supplements. Under this law, supplements can be marketed without proof of safety or efficacy as long as no claim is made for their use in the diagnosis, treatment or cure, or prevention of disease. Manufacturers can, however, make "structure and function" claims that a product enhances a normal body function or state such as thinking, mood, or immune function. For example, saw palmetto can be marketed to support urinary tract health but not to treat benign prostatic hyperplasia. In contrast to prescription drugs, the US Food and Drug Administration (FDA) must first prove that an herbal preparation is *unsafe* before it can order that a product be taken off the market.

Quality Assurance

In the past, consumers had no guarantee of the quality of the products they purchased. They could not be certain that the plant was accurately identified; that the product was free of microbial, pesticide, and heavy metal contamination; or that all batches contained the same ingredients in the same strengths.

Such lack of consistency prompted the Institute of Medicine to call on the government to implement improved quality-control manufacturing standards for supplements, more accurate labeling requirements, and greater consumer protections. In June 2007, the FDA announced that dietary supplement manufacturers must now evaluate the identity, purity, strength, and composition of their products and report all serious adverse events. These new good manufacturing practices must be phased in by June 2010.

Patients should be advised to follow certain guidelines when considering whether to use herbal medicines (Table 41–1).

Table 41–1. Advice to patients using herbal medicines.
Communication
Discuss use of all therapies with your health care provider.
Product Quality
Manufacturers are not required to submit evidence to the FDA or any regulatory body to demonstrate product safety, effectiveness, or product quality but must begin to do so (at least for adverse events) by 2010.
Ask your primary care provider, a pharmacist, or a trained herbalist regarding the specific herbs you are using.
Use herbs that are standardized to contain a specific quantity of the active ingredients.
Select formulations that have been studied in clinical trials.
Select formulations that have been independently tested for quality.
Labeling
Look for a seal of approval from an independent testing

agency such as National Products Association (formerly National Nutritional Food Association), NSF International (formerly National Sanitation Foundation), or ConsumerLab.
It should state the common and scientific names of herb(s).
It should state the concentration or dose of the herb(s) and provide instructions on dose and frequency.
It should state that the product is "standardized" to contain a certain amount of the active ingredient(s).
It should state the methods used to ensure product quality.
It should state the name and address of the manufacturer.
It should state the batch or lot number and the expiration date.
It should list potential side effects and interactions.
Pregnancy
Few herbs have been studied for safety during pregnancy.
Seek advice from your primary care provider before using herbs during pregnancy.
Interactions
Discuss with your health care provider the safety profile and interactions that may occur when combining herbs

and when taking herbs plus drugs.
Reporting
Report any adverse reactions to your state poison control program or the FDA.

FDA, Food and Drug Administration.

Product Formulations & Standardization

Herbal formulations include liquids (extracts, tinctures, infusions, and decoctions) and fresh, dried, and powdered preparations. The potency of herbs varies widely depending on which part of the plant is used, where it is cultivated, and what variations there may be in growing conditions and methods of preparation.

To ensure a consistent percentage of the primary active ingredients across batches and brand names, standardized extracts have been developed. Since multiple constituents may have pharmacologic activity, determining the active ingredients for standardization purposes can be a difficult task. In addition, ensuring stability of these active ingredients can be challenging. In a recent study of St John's wort for attention deficit/hyperactivity disorder in children, the product used in the trial was retested at the end of the trial and found to deliver only 50% of the intended dose. The European scientific community has played a significant role in producing and investigating high-quality standardized extracts that contain consistent quantities of marker compounds (ideally, the active ingredients). This work has laid the foundation for conducting phase 2 and phase 3 clinical trials. The quality of research in the field is improving, but most herbal remedies have not been evaluated in controlled clinical trials.

Safety of Herbal Medicines

Although many medicinal herbs are relatively safe, some have significant toxicity. Herbs themselves can have unanticipated effects such as hepatotoxicity as seen with chaparral and germander. Ten of twenty patients with fulminant hepatic failure referred to a liver transplant service over a 21-month period were recent or active users of potentially hepatotoxic supplements. Ma-huang contains ephedrine and was sold as a component of many weight loss products and in a banned euphoriant called "herbal ecstasy." Over 800 adverse events associated with ma-huang have been reported, including the widely publicized death of a US major league baseball player in 2003, causing the FDA to ban ephedra-containing products from the market. Herbal products may also be intentionally adulterated with prescription drugs or contaminated with harmful substances such as pesticides or heavy metals. Prescription drugs such as prednisone, nonsteroidal anti-inflammatory drugs (NSAIDs), antibiotics, and testosterone have been detected in imported Chinese patent medicines. In December 2008, the FDA issued a warning that 25 weight loss products available over the counter and on the Internet contained undeclared, active pharmaceutical ingredients, such as sibutramine, that could put consumers' health at risk.

Twenty-five percent of patients who take prescription medications also take at least one nonvitamin dietary supplement, creating a potential risk for adverse drug-herb or drug-supplement interactions. This figure increases to 50% in older US adults who take prescription medications, putting 1/25 of them at risk for developing a major drug-supplement interaction. Proving that a side effect experienced by a patient taking a dietary supplement is caused by that supplement is often difficult. Practitioners should take a detailed history from the patient and, if possible, obtain a sample of the product to facilitate further analysis, if needed. All suspected adverse events should be reported to the FDA's Medwatch Program (http://www.fda.gov/medwatch), although it is estimated that less than 1% are actually reported.

Review of the Evidence for Selected Herbal Medicines

Table 41–2 provides an overview of selected herbal medicines.

Table 41–2. Overview of selected herbal medicines.

	Leading Indications	**Dosage**	**Level of Evidence[1]**	**Safety[2]**	**Interaction; Side Effects**	**Comments**
Echinacea (purple coneflower)	1. Treatment of URIs 2. Prevention of	300 mg, or 3 mL q3–4h	1. B 2. C	I	None known: rash, pruritus, nausea	Avoid in immunocompromised patients; avoid use > 4 weeks

	URIs					
Black cohosh	Menopausal symptoms (hot flashes)	Depends on formulation (Remifemin = 20 mg twice daily)	B	I		Case reports of hepatitis, so avoid in liver disease
Garlic (*Allium sativum*)	1. Cholesterol 2. Hypertension 3. Coronary artery disease	600–900 mg once daily	1. B 2. C 3. C	I	1. Odor, flatulence 2. May have antiplatelet activity	
Ginkgo biloba (EGb	1. Dementia	60 mg three times daily	1. A 2. A	II	May have anticoagulant	Do not use in patients taking anticoagula

761, GBE)	2. Claudication				effect	nts and use caution if allergic to urushiols (mango rind, sumac-poison ivy, cashew nuts)
Asian ginseng (*Panax ginseng*)	Stamina, aphrodisiac, fertility, "tonic," "energy-booster," "adaptogen"	200–600 mg once daily extract; 1–2 g crude drug	C multiple studies but few for any given indication	I	Previous reports of toxicity have been attributed to adulterants	
St. John's wort	1. Depression:	300 mg three	1. A 2. B	I (but significant	Induces cytochr	Cyclosporine, protease inhibitors,

(*Hypericum perforatum*)	mild to moderate 2. Depression: major	times daily		drug-herb interaction)	ome P450, leading to lower serum levels of certain drugs	oral contraceptives, warfarin, digoxin levels reduced
Saw palmetto (*Serenoa repens*)	Benign prostatic hyperplasia	160 mg twice daily	B: small or none	I	Mild GI upset and headaches (rare)	Does not effect PSA levels or prostate size

[1] Level of evidence: A, high quality: consistent evidence from randomized trials or overwhelming evidence from other sources; B, moderate quality: evidence from randomized trials with important limitations or very strong evidence of some other form; C, low quality: evidence from observational studies or randomized trials with serious methodologic flaws.

[2] Safety: I, generally safe; II, relatively safe; III,

insufficient evidence; IV, may be harmful; V, clear evidence of harm.

GI, gastrointestinal; PSA, prostate-specific antigen; URI, upper respiratory infection.

St. John's Wort (*Hypericum perforatum*)

Over the past two decades, St. John's wort has been studied in thousands of patients for the treatment of mild to moderate depression. Most preparations are standardized to hypericin or hyperforin. The precise mechanisms of action are not known but are postulated to include selective inhibition of serotonin, -aminobutyrate, norepinephrine, and dopamine reuptake in the central nervous system.

Most of the 60-plus randomized controlled clinical trials, systematic reviews, and meta-analyses, including a 2008 Cochrane review, have shown that St. John's wort is more effective than placebo and as effective as prescription antidepressants for the treatment of mild to moderate depression. In addition, a standardized European hypericum extract helped prevent relapse of depression in patients who responded initially to the extract. Pooled analyses of six recent, large trials restricted to patients with major depression, however, showed only minimal effects of St. John's wort compared with placebo. A 4-year NIH study of 300 patients with mild symptoms of depression began in 2003. Patients are being randomized to St. John's wort, placebo, or citalopram for 12 weeks.

St. John's wort is generally well tolerated. Side effects are not common but include mild headache, photosensitivity, gastrointestinal upset, and restlessness. Data from 35 double-blind randomized trials show that drop out and adverse event rates in patients receiving *Hypericum* extracts were similar to placebo, lower than with older antidepressants, and slightly lower than with selective serotonin reuptake inhibitors (SSRIs). Patients are advised to avoid taking St. John's wort in combination with prescription antidepressants, as there have been case reports of the serotonin syndrome. St. John's wort also induces the cytochrome P450 system (isozyme CYP3A4), which may lower the blood levels of nearly 50% of prescription medications that are metabolized by this system (eg, ethinyl estradiol, warfarin, cyclosporine, statins, and indinavir). St John's wort can also lower the serum level of other medications by affecting the p-glycoprotein transporter system. Several cases of cardiac and renal organ rejection have been reported in patients whose previously stable level of cyclosporine was lowered after initiation of St. John's wort. Of further concern is that this herb-drug interaction may persist even after St. John's wort is discontinued. A 40% decrease in serum levels of the chemotherapeutic agent irinotecan noted in five patients taking concurrent St. John's wort

persisted for 3 weeks after St. John's wort was discontinued.

Garlic

Garlic is one of the top-selling herbs in Europe and the United States. It has been used since antiquity for the treatment of cardiovascular and infectious diseases. The German Federal Health Agency Commission E and the European Scientific Cooperative on Phytotherapy have approved its use for the treatment of hyperlipidemia and atherosclerosis. Garlic is available in multiple over-the-counter formulations (dried, powdered, oils). Many products are standardized to yield 0.6% allicin, the ingredient believed responsible for its odor and therapeutic benefit. Allicin is formed by the action of allinase enzymes when garlic is crushed. Both heat and acid destroy these enzymes, so some experts recommend that garlic is best ingested raw. The best-studied form is an enteric-coated capsule of dehydrated garlic. Freeze-drying helps retain most of the active ingredients found in raw garlic. Enteric coating permits allicin to be released in the small intestine, thereby enhancing absorption and reducing the breath odor. Allicin yield among powdered preparations varies as much as 230-fold in brands used in trials. This lack of standardization may contribute to inconsistent results in dozens of clinical trials.

Several mechanisms for garlic's beneficial effects on cardiovascular disease have been proposed: decreased low-density lipoprotein cholesterol (LDL-C) synthesis and oxidation, decreased platelet aggregation, decreased inflammation, lowered blood pressure, and antibacterial activity.

Doses of 600–900 mg of freeze-dried garlic (equivalent to one-half to one clove) taken for 4–6 weeks lower total cholesterol and LDL-C levels by 4–12%, have minimal effect on blood pressure (< 10 mm Hg, with greater decreases in subjects with hypertension), and no effect on glucose levels. In a well-designed 2007 trial, 192 adults with moderate hypercholesterolemia were randomized to one of four treatment arms for 6 months: raw garlic, two popular garlic supplements, or placebo. None of the three forms of garlic given at approximate doses of a 4-g clove garlic/d, 6 days/week for 6 months had statistically or clinically significant effects on plasma lipids in adults with initial LDL-C levels of 130–160 mg/dL. In addition, a double-blind randomized study in which 90 overweight smokers were randomized to 2.1 g/d garlic powder, 40 mg/d atorvastatin, or placebo for 3 months, showed no significant effect of garlic on inflammatory biomarkers, endothelial function, or lipid profile compared with placebo. Numerous observational studies have suggested that regular consumption of garlic might reduce the risk of developing certain malignancies, but no prospective controlled trials have been performed.

Garlic is well tolerated and apparently safe for long-term use. In addition to the well-known breath and body odor, common side effects include gastrointestinal upset, nausea, and flatulence.

A more than 50% reduction in blood levels of saquinavir after garlic supplementation has been reported. Although the induction of the cytochrome P450 system was hypothesized as the mechanism of action of this significant herb-drug interaction, a recent study of healthy volunteers did not reveal an effect of garlic on isozymes CYPP2D6 or CYP3A4. Garlic has been shown to have some antiplatelet activation activity, so there is a theoretical risk of increased bleeding, especially if taken with aspirin, anticoagulants, or NSAIDs. However, a 2006 study of 48 patients taking warfarin randomized to aged garlic extract or placebo for 12 weeks did not report any increased bleeding in those taking garlic. In addition, a 2008 study showed no effect of garlic on warfarin pharmacokinetics in healthy volunteers. No changes in platelet function were noted in healthy volunteers after ingesting raw garlic and garlic oil, but some clinicians recommend stopping garlic 1–2 weeks prior to undergoing elective surgery.

Ginkgo

The dried leaf of the ginkgo tree has been used medicinally for thousands of years. More than 400 studies over the past 30 years have investigated ginkgo's ability to improve blood flow in a variety of conditions, including memory impairment, dementia, peripheral vascular disease, vertigo, tinnitus, asthma, SSRI-induced sexual dysfunction, anxiety and acute mountain sickness. It is the sixth best selling herb in the United States with greater than $250 million in sales per year. The German Commission E has approved a standardized form of ginkgo leaf extract (EGb 761) for the treatment of cognitive impairment and intermittent claudication. Multiple pharmacologically active compounds have been isolated from ginkgo. Flavonoids have antioxidant and free radical scavenging ability and terpene lactones have platelet-activating factor antagonist activity. In addition, ginkgo extracts increase the production of nitric oxide and activate certain central neurotransmitters, including the cholinergic system, which may contribute to their beneficial effects on memory and cognition. EGb 761—the formulation that has been studied most extensively—is standardized to contain 24% flavonoid glycosides and 6% terpene lactones.

Early studies that assessed ginkgo's efficacy on cognitive function in the elderly showed a modest improvement when compared with placebo. The longest of these studies (1 year) showed stabilization of cognitive and functional abilities in 309 demented patients treated with EGb 761 compared with placebo, with no differences in adverse outcomes. A 2007 systematic review, however, concluded that ginkgo did not have predictable and clinically significant benefits in patients with dementia. A well-designed NIH-funded study also showed that ginkgo (120 mg EGb721 twice a day) did not prevent dementia in more than 3000 elderly subjects with normal or mildly impaired cognitive function who were monitored for a mean of 6 years. A smaller study also failed to show any reduction in progression to dementia in 118 subjects 85 years of age or older who were randomized to 80 mg of a different formulation of ginkgo three times a day or placebo for 42 months. When researchers took into account participant's adherence, however, the group that actually took their ginkgo had a smaller decline in memory compared with those taking a placebo. There is conflicting evidence about ginkgo's ability to enhance memory in healthy individuals. In general, ginkgo is well tolerated in healthy adults at recommended doses for up to 6 months. Allergic skin reactions, gastrointestinal disturbances, and headache occur in less than 2% of patients. There are theoretical concerns about a risk of increased bleeding because antiplatelet activating factor activity has been demonstrated in vitro. Nearly 20 cases of increased bleeding in patients taking ginkgo have been reported, but establishing a causal relationship is challenging because many of these patients had other risk factors including age and use of medications, such as warfarin, aspirin, or NSAIDs. Of note, no excess bleeding complications have been reported in clinical trials and no differences in coagulation, platelet function, or pharmacokinetics of warfarin have been reported in healthy volunteers. Caution should still be exercised in patients with bleeding disorders or who are taking anticoagulants, aspirin, or other herbs that may increase the risk of bleeding. In one study, ginkgo (90 mg/d) did not show any adverse effects on the pharmacokinetics of donepezil (5 mg/d) when administered together, but potential interactions with other medications used to treat dementia are not known.

Ginkgo has also been evaluated for its effect on intermittent claudication. A meta-analysis of nine randomized, placebo-controlled, double-blinded trials of patients treated with EGb761 showed a modest treatment effect in the increase of pain-free walking distance in favor of ginkgo over placebo. There is insufficient evidence to support ginkgo's efficacy in treating tinnitus, acute mountain sickness, vertigo, or SSRI-associated sexual dysfunction.

Echinacea

Echinacea ranks third among the top-selling herbs in the United States, accounting for more than $300 million in sales annually. Three of nine *Echinacea* species are currently used for the treatment and prevention of upper respiratory infections. Preparations are made from roots (*Echinacea pallida* and *Echinacea angustifolia*), above-ground parts (stems, leaves, and flowers of *Echinacea purpurea*), or a combination of both. Multiple forms are available over-the-counter, including capsules, fresh pressed juice, tinctures, and teas. Differences in species, growing conditions, plant parts used, and extraction procedures can result in differences in chemical composition and biologic activity. Several active ingredients have been identified, including polysaccharides, glycoproteins, alkaloids, and flavonoids. In vitro, animal, and human studies suggest that these ingredients cause stimulation of the immune system and that they possess anti-inflammatory, free radical-scavenging, and antiviral activity.

The quality of most clinical trials has been limited by use of multiple products and doses (including formulations containing multiple herbs) and the lack of rigorous methodology.

The majority of early trials reported that echinacea is effective in reducing the duration and severity of colds if started within several days of the onset of symptoms but no more effective than placebo when taken to prevent infection. A well-designed, 2005 trial studied three different *E angustifolia* root preparations for the prevention and treatment of laboratory-induced rhinovirus infections. Four hundred thirty-seven volunteers were randomized to receive either prophylaxis (beginning 7 days before a challenge with rhinovirus) or treatment (beginning at the time of viral challenge), with one of the three different echinacea preparations. No statistically significant effects were seen on rates of infection or severity of symptoms in patients taking the herb. The echinacea used in this trial was well characterized and of high quality, but some clinicians feel that the dose used was lower than that used in routine practice. In contrast, an updated meta-analysis of echinacea monopreparations found that 10 of 16 trials showed the herb to be more effective than placebo for the treatment of colds, particularly preparations made from above-the-ground parts of *E purpurea*. Authors of a 2007 meta-analysis of 14 clinical trials also conclude that echinacea is beneficial in decreasing both the incidence and duration of the common cold. The herb decreased the odds of developing a upper respiratory tract infection by 58% and the duration of a cold by 1.4 days. In contrast, *E pallida* was no more effective than placebo in decreasing the risk of ear infections in children prone to otitis media. In general, echinacea is well tolerated, with few reported adverse events. Rare allergic reactions including rash have been reported (especially in patients with ragweed allergies), and there was a single case of recurrent erythema nodosum. The German Commission E recommends that patients who are pregnant, have autoimmune disease, or who are immunocompromised not take echinacea because of its immune-stimulating effects. The Commission also recommends that its use be limited in others to less than 4 weeks. The data supporting these recommendations are not clear.

Ginseng

Ginseng root has been used for medicinal purposes in Asia for over 2000 years and is consumed by up to 5% of the population in Western countries. Two major forms of ginseng are in use today: Asian ginseng (*Panax ginseng*) and American ginseng (*Panaxquinquefolius*). *Eleutherococcus senticosus* (previously known as Siberian ginseng), is not a member of the *Panax* genus and does not contain ginsenosides that are thought to be the active ingredients in true ginseng. The German Commission E monograph on ginseng root approves its use as "a tonic to counteract weakness and fatigue, as a restorative for declining stamina and impaired concentration, and as an aid to convalescence." Extracts are made from dried roots and contain more than 25 ginsenosides, each with unique and sometimes oppositional effects on the cardiovascular, central nervous, and immune systems. The mechanisms of action have not been clearly delineated.

Multiple indications have been studied using different ginseng species, often with poor methodologic rigor. One European study identified 57 randomized controlled trials of ginseng in the world's literature, but only 16 studies were of good enough quality to be included in their systematic review. Insufficient evidence was available to support or refute the use of ginseng for any of the purported indications, including improvement of physical performance, cognitive functioning, and quality of life. In contrast, a small open label 2008 trial suggests that Korean red ginseng (unskinned Panax ginseng before it is steamed and dried) may improve cognitive function in patients with Alzheimer disease. Some early studies suggest that ginseng causes small reductions in blood pressure, but there was no effect on 24-hour blood pressure or kidney function in 52 hypertensive patients who took North American ginseng for 12 weeks. A 2006 systematic review of 34 studies also did not support the use of ginseng to treat cardiovascular risk factors, although at least 7 human studies since 2000 report that American and Asian ginseng may lower blood glucose in both healthy and diabetic patients. Ginseng is believed by many to enhance sexual function. A systematic review of 7 randomized clinical trials of Korean red ginseng concluded there was suggestive evidence for effectiveness in treating erectile dysfunction, although the quality of these studies was low.

Ginseng is well tolerated at recommended doses, with few adverse effects. A recent systematic review of adverse reactions reports that the incidence is similar in ginseng monopreparations and placebo. Possible drug interactions have been reported between *P ginseng* and warfarin, phenelzine, calcium channel blockers, digoxin, and alcohol. A potential risk of hypoglycemia exists in diabetic patients taking medications. Earlier reports of "ginseng abuse syndrome" and other toxicities are now attributed to adulterants found in earlier unregulated over-the-counter ginseng products. Indeed, 13 of 21 ginseng products recently evaluated for quality and purity failed because they contained unacceptable levels of pesticides or heavy metals or inadequate concentrations of ginsenosides.

Saw Palmetto

Saw palmetto is used by over 2 million men in the United States to treat benign prostatic hyperplasia (BPH), and in Europe, it is often the first-line therapy for lower urinary tract symptoms. Lipophilic extracts are prepared from the berries of the dwarf palm tree (*Serenoa repens*) and are standardized to sterols and free fatty acids. Several mechanisms of action have been proposed, including inhibition of 5 -reductase activity, as well as antiandrogenic, anti-inflammatory, and antiproliferative activity. More than 350 saw palmetto products are marketed in the United States; however, the most studied brand of saw palmetto (Permixon) is not available.

Early studies showed that saw palmetto was more effective than placebo and only slightly less effective than -blockers for the treatment of BPH. In a 2008 trial of 92 Chinese men with lower urinary tract symptoms associated with BPH, those treated with saw palmetto for 3 months had significantly greater urine flow rates and improved symptoms relative to those taking the placebo. In contrast, a well-designed 2006 trial showed no difference in symptom scores, flow rates, prostate size, postvoid residual volume, quality of life, or prostate-specific antigen in 225 men with moderate to severe BPH treated with saw palmetto (160 mg twice daily) or placebo for 1 year. An even larger (3000 patient), 4–6 year long, multicenter, three-arm randomized, controlled trial of saw palmetto, the herb *Pygeum africanum*, and placebo is being sponsored by the NIH.

Saw palmetto is very well tolerated by most patients, with only mild and rare gastrointestinal symptoms being reported. It has not been shown to reduce prostate size or lower the serum level of prostate-specific antigen. No herb-drug interactions have been reported.

Black Cohosh

Black cohosh, a member of the buttercup family, is a plant native to North America that has gained popularity as a nonhormonal treatment for menopause-related symptoms. Preparations made from its roots and rhizomes were used by Native Americans to treat malaise, genitourinary complaints, colds, and rheumatism. Its mechanism of action remains unclear, but it does not appear to have significant estrogenic effects in vitro or in vivo. A recent report suggests that it acts on the human opioid mu receptor, which may play a role in regulating body temperature.

Black cohosh has been studied in more than 3000 women. The most widely used formulations are two German-manufactured preparations. Fifteen clinical trials have shown efficacy for Remifemin, an isopropanoic extract available since the mid-1950s, and six trials have studied a different product, marketed as Klimadynon. Many clinical trials published since 2003 demonstrate efficacy of black cohosh for reducing menopausal symptoms such as hot flashes, including a 2007 study in which it was as effective as tibolone (a synthetic steroid only available in Europe). In contrast, a year-long trial published in late 2006 did not show that black cohosh alone or in combination with other herbs was any more effective than placebo in reducing hot flashes or night sweats. In this five-arm trial, 351 women, age 45–55 with at least two hot flashes per day, were randomized to receive black cohosh, a combination of black cohosh and nine other herbs, the combination product along with counseling to increase soy consumption, placebo, and conventional hormone replacement therapy (HRT). (The HRT arm was terminated when the Women's Health Initiative trials were prematurely halted in 2002.) A smaller 2008 trial of a preparation containing black cohosh and Chinese herbs also showed no reduction in hot flashes compared with placebo.

Black cohosh is generally well tolerated at recommended doses. Rare case reports of hepatitis have been reported (some severe enough to require liver transplantation), causing the Medicines and Healthcare Registry Agency in Britain to join Australia in requiring that products be labeled with a safety warning. The NIH held a workshop on the safety of black cohosh in 2004 and concluded that there was inadequate evidence of a causal relationship between black cohosh and hepatotoxicity, although they did recommend that liver enzymes be monitored in all participants in NIH-sponsored trials of black cohosh. No significant drug-herb interactions have been reported.

A 2006 analysis of 11 black cohosh products available in the United States revealed that 4 contained a cheaper Asian species, which has different chemical properties, either as the sole ingredient or in combination with North American black cohosh.

Dietary Supplements

Sales of dietary supplements have increased dramatically over the past decade. The Dietary Supplement Health Education Act of 1994 has made it possible for manufacturers to sell dietary supplements directly to the public without FDA approval or oversight. Reports of adulteration and contamination are available, but the magnitude of this problem remains unknown. Furthermore, there have been several reports of the dose printed on the label being different from the actual dose provided. (See section on herbal medicines, above, for further details on regulatory and quality assurance issues and advice for patients to follow when purchasing these products.) Table 41–3 provides an overview of selected dietary supplements commonly used in the United States today.

Table 41–3. Overview of selected dietary supplements.

	Leading Indications	**Dosage**	**Level of Evidence**[1]	**Safety**[2]	**Interactions; Side Effects**	**Comments**
Melatonin	1. Insomnia 2. Jet lag	0.1–5 mg	1. B 2. B	I	None	
Dehydroepiandrosterone (DHEA,	1. Depression,	50 mg once daily	1. C 2. B	IV (with	None reported;	Theoretical concer

DHEAS)	dysthymia 2. Lupus 3. Adrenal insufficiency		3. C	long-term use)	androgenic effects	ns that long-term use may result in hormone-dependent malignancies
Omega-3 fatty acids (fish oil)	1. High triglycerides 2. Coronary heart disease 3. Inflammatory conditions	Fish twice weekly for general health (300–500 EPA plus DHA) 1 g/d for	1. A 2. B 3. C	III	Theoretical risk of bleeding at high doses	

		heart disease				
Glucosamine sulfate and chondroitin	Osteoarthritis (knee)	Glucosamine 500 mg three times daily; chondroitin 400 mg three times daily	B	I	None reported; rare reports of constipation, diarrhea, drowsiness	Insulin resistance not seen in clinical trials
Coenzyme Q_{10} (ubiquinone, ubidecarenone, Co-Q_{10})	Congestive heart failure, cardiac arrest, angina, acute myocardial infarcti	50 mg once daily–150 mg three times daily; goal is to achiev	C	I	Patients taking statins noted to have lower serum levels of Co-Q_{10}	Fat-soluble, so absorption improved when taken with meals

	on, migraine prophylaxis	e serum level of 2.1 mcg/mL				

[1] Level of evidence: A, high quality: consistent evidence from randomized trials or overwhelming evidence from other sources; B, moderate quality: evidence from randomized trials with important limitations or very strong evidence of some other form; C, low quality: evidence from observational studies or randomized trials with serious methodologic flaws.

[2] Safety: I, generally safe; II, relatively safe; III, insufficient evidence; IV, may be harmful; V, clear evidence of harm.

EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid.

Dehydroepiandrosterone

Dehydroepiandrosterone (DHEA) and its metabolite, DHEAS, are secreted by the adrenal cortex and serve as precursors for the synthesis of more than 40 different hormones, including male and female sex hormones. In healthy individuals, DHEA levels fall 10–15% per decade from age 20 until age 70, when they are at 30% of lifetime peak levels. Normal circulating levels vary widely by age, sex, and ethnicity and are affected by body mass index, medications (insulin, corticosteroids, opioids), and thyroid function. Reduced levels of DHEA have been reported in people who suffer from a wide variety of chronic illness, including depression, cancer, type 2 diabetes, HIV infection, Alzheimer disease, lupus erythematosus, chronic kidney disease, anorexia, and atherosclerosis. Low levels of DHEA associated with aging and medical illness have been cited in the popular press as evidence that DHEA supplementation might be beneficial.

The mechanism of action of DHEA remains unknown. Animal studies suggest that DHEA and DHEAS have excitatory effects on the central nervous system, which may account for their influence on mood and sense of well-being. A 6-week clinical trial randomized 52 persons with major or minor depression to monotherapy with DHEA or placebo and found DHEA to be superior as measured by multiple well-validated depression scales.

Animal studies suggest that DHEA and DHEAS have excitatory effects on the central nervous system, which may account for their influence on mood and sense of well-being. A 6-week clinical trial randomized 52 persons with major or minor depression to monotherapy with

DHEA or placebo and found DHEA to be superior as measured by multiple well-validated depression scales.

Low DHEA levels in men and women with systemic lupus erythematosus (SLE) and reduction in interleukin-10 levels after supplementation compared with placebo suggest that DHEA may play a causative role. A 2007 systematic review of seven clinical trials of DHEA in SLE patients concluded that it had modest but clinically significant impact on health-related quality of life measures in the short term. Several studies suggest that DHEA supplementation improves physical and psychological well being in healthy persons, but several well-designed trials have shown that DHEA supplementation has no effect on cognitive performance, body composition, physical performance, or well-being in healthy older adults.

DHEA modestly increases testosterone levels in women, but not in men, unless they have hypogonadism. Side effects include acne, deepening of the voice, and facial hair growth. No serious adverse events have been reported. The long-term effects of DHEA supplementation remain unknown. The safety issue of most concern is that DHEA—as a potent precursor of sex steroids—may increase the risk of estrogen- or androgen-dependent malignancies. Therefore, if supplementation is used, patients should be screened carefully and monitored closely. Furthermore, patients at high risk for prostate, ovarian, breast, or uterine cancer should be counseled against DHEA supplementation.

Glucosamine & Chondroitin

Glucosamine and chondroitin have been used in Europe alone and in combination to treat osteoarthritis since the 1980s. Glucosamine is an amino sugar synthesized by chondrocytes that serves as a substrate for the synthesis of cartilage. In addition to providing structural support, it may also have anti-inflammatory activity. Chondroitin is a glycosaminoglycan normally present in the cartilage matrix that helps maintain articular fluid viscosity, inhibit enzymes that break down cartilage, and stimulate cartilage repair. Glucosamine is prepared commercially from crustacean shells. Chondroitin is extracted from bovine tissues such as cow trachea.

A 2007 meta-analysis concluded that use of chondroitin by itself to treat knee or hip osteoarthritis was not warranted in routine clinical practice.

Two meta-analyses and a 2005 Cochrane Review of 20 randomized, double-blind, placebo-controlled trials involving more than 2570 patients with osteoarthritis support the use of glucosamine (or glucosamine and chondroitin) in the treatment of osteoarthritis of the knee. The Cochrane Review identified efficacy only for trials using a once daily proprietary formulation manufactured by Rotta Pharmaceuticals. In the longest trial using the Rotta formulation, glucosamine not only reduced the symptoms of osteoarthritis of the knee but also slowed the progression of the disease. Reginster and coworkers randomized 212 patients to receive 1500 mg/d of glucosamine or placebo. After 3 years, patients taking glucosamine reported a 24% reduction in symptoms versus a 10% increase in the placebo group. Radiographs revealed that the treatment patients experienced a loss of only 0.06 mm joint space versus 0.31 mm in the placebo group after 3 years. A 2006 randomized controlled trial that examined the efficacy of a non-Rotta glucosamine preparation, however, came to a different conclusion. The Glucosamine/chondroitin Arthritis Intervention Trial (GAIT) was a multicenter randomized double-blind placebo-controlled clinical trial in which 1583 persons were randomized to glucosamine hydrochloride, chondroitin sulfate, glucosamine hydrochloride plus chondroitin sulfate, celecoxib, or placebo. Investigators found no difference overall between the supplements alone or in combination and the placebo at 24 weeks. In a predefined subgroup of patients with moderate to severe pain, however, combined therapy with glucosamine and chondroitin did provide greater pain relief than placebo. When joint-space narrowing was evaluated in a subset of patients who continued in the study for a total of 2 years, glucosamine and chondroitin, alone or in combination, were no better than placebo in slowing the loss of knee cartilage. The generalizability of these results may be limited by the fact that glucosamine hydrochloride was used and patients in the placebo group had less cartilage loss than predicted. In contrast, the 2007 European GUIDE Trial (Glucosamine Unum in Die Efficacy Trial) studied the once daily proprietary formulation of crystalline glucosamine sulfate and found that after 6 months it was more effective than placebo in relieving the symptoms of knee osteoarthritis.

Fewer clinical data are available for patients with osteoarthritis of other joints. In a well-designed 2008 study, 222 patients with mild to moderate osteoarthritis of the hip were randomized to 1500 mg/d of glucosamine sulfate or placebo. Glucosamine had no clinically significant effect on pain, function, or joint space narrowing after 2 years.

Oral glucosamine is generally well tolerated and does not elevate serum glucose levels in humans. No significant drug-herb interactions have been reported, except a possible increase in INR in patients taking glucosamine and warfarin together. In contrast to NSAIDs, glucosamine may take weeks to months before improvement in symptoms is noticed. In summary, clinical trial literature suggests that glucosamine with or without chondroitin is well tolerated and safe with fewer side effects than NSAIDs. However, the efficacy of formulations other than a proprietary European product in the treatment of osteoarthritis remains in question.

Coenzyme Q_{10}

Coenzyme Q_{10} (also known as ubiquinone-10) is a fat-soluble provitamin that resides in the lipid layer of the mitochondria. It plays a crucial role in electron and proton transfer during oxidative phosphorylation and production of adenosine triphosphate (ATP), so it is necessary for the basic functioning of all cells. It also has antioxidant, free radical scavenging, and membrane stabilizing activities. Coenzyme Q_{10} levels decrease with age. Deficiencies have been observed among patients with certain chronic medical conditions, including cardiovascular disease (hypertension, acute coronary syndromes, congestive heart failure), renal failure, male infertility, periodontal disease, cancer, HIV/AIDS, muscular dystrophies, Parkinson disease, and Alzheimer disease. Certain prescription medications may also lower coenzyme Q_{10} levels, including HMG-CoA reductase inhibitors, diabetes medications, -blockers, diuretics, and antidepressants. Serum levels of coenzyme Q_{10} are increased by taking supplements, but there are conflicting data about whether this results in clinical benefit.

In parts of Russia, Europe, and Japan, coenzyme Q_{10} is part of standard therapy for congestive heart failure, although it is not recommended for treatment of congestive heart failure by the American College of Cardiology or the American Heart Association. Other studies have evaluated coenzyme Q_{10} for acute myocardial infarction, angina, diabetes mellitus, hypertension, migraine prophylaxis, muscular dystrophy, Parkinson disease and periodontal disease with mixed results. A 2006 Cochrane systematic review of treatments for mitochondrial disorders describe two trials of coenzyme Q_{10}, one reporting subjective improvement and significant increase in a scale of muscle strength but the other showing no benefit. Although other medical conditions are also associated with low levels of coenzyme Q_{10}, additional randomized controlled clinical trials are needed before supplementation with coenzyme Q_{10} can be routinely recommended to improve outcomes for any particular condition.

Because coenzyme Q_{10} is lipophilic, it is often formulated with vegetable oil or vitamin E to enhance its absorption. Its bioavailability is also enhanced when it is taken with meals, especially fat-rich foods. No serious adverse events have been noted with coenzyme Q_{10} use, and it is generally well tolerated. Insomnia, elevated liver enzymes, rash, and abdominal complaints are among the mild adverse reactions reported in clinical trials. No significant drug-herb interactions have been reported, but coenzyme Q_{10} is chemically similar to vitamin K and so theoretically may reduce the effectiveness of warfarin.

Omega-3 Fatty Acids

Interest in omega-3 fatty acids began 30 years ago, when it was discovered that the Inuit population of Greenland had low rates of cardiovascular disease, despite consuming a high protein and high fat diet (mostly in form of fish). Evidence from multiple large-scale observational studies and randomized controlled trials indicates that intake of fish or fish oil supplements (or both) containing the omega-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) is associated with many health benefits. A recent review concluded that modest consumption of fish (1–2 servings per week), especially species higher in the omega-3 fatty acids EPA and DHA, reduces the risk of coronary death by 36% and total mortality by 17%. Multiple mechanisms have been proposed for the beneficial effects of omega-3 fatty acids for both primary and secondary prevention of cardiac disease. These include reductions in triglyceride levels, inflammation, blood pressure (2–5 mm Hg), blood clotting, arrhythmias, atherosclerotic plaque formation, and improvements in arterial and endothelial function. The reduction in triglyceride levels appear to be dose-dependent, with effects at doses as low as 2 g/d. Higher doses have greater effects, and 4 g/d can lower triglyceride levels by 25–40%.

Several well-conducted, randomized controlled trials report that in individuals with a history of heart attack, regular consumption of oily or fish oil/omega-3 supplements reduces the risk of nonfatal heart attack, fatal heart attack, sudden death, and all-cause mortality. Benefits have been reported beginning after 3 months of use, and for as long as 3.5 years of follow-up. Recent data suggest that omega-3 fatty acids may be more effective than statins in treating congestive heart failure. Although fish oils have been studied primarily in patients at risk for cardiovascular disease as well as those with established cardiovascular disease, they are also being investigated in treatment of other conditions such as diabetes, dementia, depression, obesity, inflammatory bowel disease, and attention deficit/hyperactivity disorder.

Animal sources of omega-3 fatty acids (EPA and DHA) include fish, especially cold-water fatty fish such as salmon, mackeral, halibut, anchovies, and sardines. A proprietary plant-based source of DHA is manufactured from algae. Vegetable sources of the omega-3 fatty acid alpha-linolenic acid (ALA) include English walnuts; flaxseeds; tofu/soy and some vegetable oils, such as canola, soy, flaxseed, and olive oil. Dietary intake of omega-3 fatty acids has declined by 80% over the past century, while intake of omega-6 fatty acids has greatly increased. Omega-6 fatty acids come from the common use of other vegetable oils (corn, safflower, and sunflower oils) containing linoleic acid; these compete with omega-3 fatty acids to be converted to active pro-inflammatory metabolites in the body.

In 2003, the American Heart Association recommended that healthy people eat fish at least twice a week as well as consume plant-derived sources of omega-3 fatty acids, such as tofu/soybeans, walnuts, flaxseed oil, and canola oil. People with known coronary heart disease should take in approximately 1 g/d of EPA and DHA (combined). The FDA regards intake of up to 3 g/d of omega-3 fatty acids from fish as safe. Fish oil supplements are widely available over the counter and should be dosed based on their content of EPA and DHA. Omega-3 fatty acid 1 g prescription capsules, containing 465 mg of EFA and 375 mg of DHA, are also FDA-approved for the treatment of hypertriglyceridemia. In a 2007 trial, addition of 4 g/d of prescription omega-3 acids to 40 mg/d simvastatin improved lipid parameters to a greater extent than simvastatin alone.

The most common side effects of fish oil supplementation are gastrointestinal upset, burping, fishy taste, loose stools, and nausea. High doses may also have harmful effects, such as an increased risk of bleeding, so the FDA recommends no more than 3 g of EPA plus DHA per day and no more than 2 g from the diet. The potential for harm from mercury, dioxins, and polychlorinated biphenyls (PCBs) present in some fish was addressed in a recent review which concluded that, in general, the benefits of fish intake exceed the potential risks.

Melatonin

Melatonin (N-acetyl-5-methoxytryptamine) is a hormone synthesized by the pineal gland from the amino acid tryptophan that is released into the circulation in response to environmental light-and-dark signals. Serum levels in humans vary 10- to 20-fold over 24 hours from a low of 2–10 pg/mL during daylight hours to a high of 100–200 pg/mL at night.

Melatonin is used to treat a variety of medical conditions, particularly insomnia and jet lag, given its role in regulating the body's circadian rhythm. Although available as an over-the-counter sleep aid in this country, it is available only by prescription in much of the rest of the world (European Union, Australia, and New Zealand).

A 2005 meta-analysis of 17 clinical trials involving 284 subjects concluded that melatonin was effective in reducing the time it took them to fall asleep and increasing the amount of time they remained asleep. The authors concluded that exogenous melatonin was helpful in treating insomnia, particularly in older individuals and those with low nocturnal levels of melatonin. An NIH State-of-the-Science Panel Report that same year also concluded that melatonin was effective in the management of chronic insomnia in subsets of the adult population.

In contrast, a 2006 meta-analysis, which included patients of all age-groups, failed to document clinically meaningful effects of exogenous melatonin on sleep quality, time to fall asleep, and hours slept per night. Nightly melatonin (2.5 mg) combined with daytime bright light was shown to modestly improve cognitive and noncognitive function in 189 elderly Dutch residents of 12 group care facilities. Melatonin was noted to have adverse effects on mood when used alone in these elderly subjects, but these effects were not observed when melatonin was used in combination with bright light.

Melatonin is believed to have antioxidant, antineoplastic, and immunomodulatory activity, but there are insufficient clinical trial data to support its use for conditions other than insomnia and jet lag. Of interest, melatonin receptors have recently been demonstrated on pancreatic islet cells, which may help explain a link between disturbed sleep and glucose intolerance.

Three melatonin receptors have been identified in mammals: MT1, MT2, and MT3. MT1 and MT2 appear to regulate the circadian sleep-wake cycle. Ramelteon, a selective MT1 and MT2 receptor agonist, was approved by the FDA in 2005 to treat insomnia.

Considerable person-to-person variability in serum levels after taking the same dose of melatonin has been reported. Physiologic doses (0.1–0.3 mg) have been shown to decrease time until sleep, increase duration of sleep, and decrease daytime fatigue. Commonly available over-the-counter doses (1–10 mg) have been reported to raise plasma concentrations to levels 3–60 times greater than normal peak levels.

Melatonin is generally considered safe at recommended oral doses of 5 mg or less for up to 2 years. No hangover effect has been noted, even after 1 month of taking high doses.

Side effects of fatigue, sleepiness, headache, dizziness, and irritability are no more commonly reported than with placebo. Caution is advised in patients taking immunosuppressants or those with vascular disorders or infertility problems.

Acupuncture

In acupuncture, anatomic points on the surface of the body are stimulated by a variety of techniques, often with needles, to treat illness and promote health. Many styles exist and are practiced as part of the thousands of years old medical traditions of China, Japan, Korea and other countries. Practitioners trained in Oriental medicine believe that a vital energy called chi (pronounced "chee") circulates in the body through 12 virtual pathways called meridians. Disease occurs when the flow of chi in the body is not in balance. Each meridian is named after a particular organ or "official." In addition to describing the structure and function of the organ itself, the naming of each meridian also reflects a broader energetic function in Traditional Chinese Medicine.

Mechanism of Action

The mechanism of action of acupuncture is not well understood, but physiologic effects can be measured when acupuncture points are stimulated, such as the release of endorphins and enkephalins. Functional MRI studies reveal that different areas of the brain are activated and deactivated during needling.

Stux G, Berman B, Pomeranz B (editors). *Basics of Acupuncture.* 5th ed. Springer, 2003.

Training, Licensure, & Regulation

Typical acupuncture training for nonphysicians in the United States involves completion of a 4-year (2500 hours) master's degree training program accredited by the Accreditation Commission for Acupuncture and Oriental

Medicine (ACAOM). In order to become a licensed acupuncturist (LAc), a national and, frequently, state board examination must be passed. Although many states do not require physicians to obtain additional training, many encourage a minimum of 200 hours of training in an accredited program. There are currently approximately 18,000 licensed acupuncture practitioners and more than 3000 physician acupuncturists in the United States. In 22 of the 43 states that license, register, or certify acupuncturists, these practitioners are permitted to work independently.

Clinical Practice

In the United States and Europe, Oriental medicine-trained practitioners conduct a comprehensive multisystem history, observation, and physical examination during the initial consultation. Examination consists of palpation of the abdomen and selected acupuncture points; examination of the tongue to assess color, shape, and coating; and palpation of the pulse along the wrist at three locations on both arms to assess its quality, rhythm, and strength. In classic acupuncture, each patient is viewed as having a unique constellation of symptoms and signs. What this means is that ten patients presenting with migraine headaches might receive ten unique Chinese medical diagnoses and ten different treatments. Because acupuncture is just one part of a comprehensive system, patients are also often prescribed Chinese herbal therapy, diet, and exercise. Western-style practitioners will conduct a conventional examination and include variable components of the Oriental medicine approach depending on the individual's depth of training. Treatment typically utilizes a fixed combination of acupuncture points for a given medical diagnosis, such that a cohort of migraine sufferers will be treated in a similar way.

Treatment typically involves inserting four to fifteen needles at selected acupuncture points for 10–30 minutes—though certain schools leave the needles in place for only a few seconds to minutes. Virtually all acupuncture is performed with thin, solid, stainless steel, sterile disposable needles that are stimulated manually or with electricity or heat. Follow-up consultations last from 20 minutes to 45 minutes. A course of treatment usually consists of weekly or biweekly visits for 4–10 weeks, followed by less frequent visits as the condition improves.

Adverse Events

The current practice of acupuncture in the United States and Europe is associated with a very low incidence of adverse events (as low as 1 in 10,000 to 1 in 100,000 needle insertions). Reactions such as presyncope, syncope, and drowsiness can be easily prevented by having the patient lie flat on the table, monitoring them during their initial visit, and permitting them to remain in the office until a normal state of awareness is achieved. Serious complications in the literature over the past 30 years are very rare but include spread of infection and pneumothorax from needling patients with emphysema.

Clinical Uses of Acupuncture

More than 1000 English-language reviews of the clinical use of acupuncture in humans have been published in the last 20 years, many pointing out the challenge of designing high-quality trials with effective placebo controls. Several types of placebos have been tried: needling at nonacupuncture points, using a retractable sham needle that does not penetrate the skin, and needling at true acupuncture points that are inappropriate for the condition being treated. Data analysis is complicated by the fact that sham treatments can have physiologic effects in and of themselves. Acupuncture has been shown to be most effective in treating pain and nausea. A 2009 systematic review, however, concluded that "whether needling at acupuncture points or at any site reduces pain independent of the psychological impact of the ritual is unclear." Recent reviews have also concluded that acupuncture is not effective (or that data were inconclusive for) treating hypertension, hot flashes, epilepsy, insomnia, allergic rhinitis, Parkinson disease, restless leg syndrome, and dyspnea. What follows is a selection of some conditions for which patients commonly seek acupuncture care.

Park J et al. The status and future of acupuncture clinical research. J Altern Complement Med. 2008 Sep;14(7):871–81. [PMID: 18803496]

Low Back Pain

More than 50 clinical trials of acupuncture for the treatment of low back pain were reviewed by the American Pain Society and American College of Physicians as part of clinical practice guidelines that were published in 2007. They concluded that there was a fair level of evidence supporting a moderate benefit of acupuncture in treating subacute (4–8 weeks) or chronic low back pain. In most studies, acupuncture has not been shown to be more effective when compared with other active treatments, but provides additional benefit when added to conventional therapies. A 2008 systematic review of 23 randomized controlled trials involving more than 6000 patients concluded that acupuncture versus no treatment and as an adjunct to conventional care should be advocated in the European Guidelines for the treatment of chronic low back pain.

Osteoarthritis

A 2006 systematic review and meta-analysis of 18 randomized controlled trials concluded that "sham-controlled trials suggest specific efficacy of acupuncture for pain control in patients with osteoarthritis of peripheral joints. The favorable safety profile makes acupuncture a worthy option of consideration, particularly for knee osteoarthritis." Acupuncture plus routine care was associated with marked clinical improvement in a German trial in which 632 patients with osteoarthritis of the hip or knee were randomized to up to 15 sessions of physician-delivered acupuncture or wait-list control for 3 months. The treatment protocol was individualized for each patient at the discretion of the physician, more closely reflecting how acupuncture is practiced clinically. One-third (34.5%) of the acupuncture-treated group had a good response after 3 months, compared with 6.5% of the wait-list control group. The improvement in pain and quality of life was maintained at 6-month follow-up.

A 2007 meta-analysis of nine clinical trials revealed clinically relevant short-term (but not long-term) improvements in pain and function compared with those in wait-list control groups. Authors concluded that some of acupuncture's clinically relevant benefits might be due to placebo and expectation effects.

A 2007 cost effectiveness trial involving almost 500 German patients who were randomized to routine care or routine care plus acupuncture concluded that acupuncture was a cost-effective treatment for osteoarthritis.

Postoperative Pain

Acupuncture was helpful in reducing pain intensity, opioid consumption, and opioid-associated side effects in a 2008 systematic review of 15 randomized clinical trials comparing acupuncture with sham control for acute postoperative pain. In contrast, a systematic review of 9 trials of auricular acupuncture concluded that the evidence was "promising but not compelling" in its reducing postoperative pain.

Headache

Mixed results were reported early on about acupuncture's efficacy in the treatment of headaches, but more recent reviews conclude that it is a safe and effective option for treating both tension and migraine headaches. A 2008 study also concluded that acupuncture was cost effective when compared with routine care in patients with primary headache.

Nausea & Vomiting

Based on multiple randomized controlled trials involving more than 6000 patients, there is strong evidence that acupuncture is effective in the treatment of pregnancy-induced, chemotherapy-induced, and postoperative nausea and vomiting. A 2006 systematic review identified 43 trials using a particular acupuncture point (P6) for treatment of nausea and vomiting. P6 is located on the anterior surface of the forearm, several inches proximal to the wrist between the tendons of palmaris longus and flexor carpi radialis. Results across trials were the most consistent for postoperative nausea and vomiting. Compared with sham procedures, P6 stimulation was more effective than comparison in preventing nausea (RR

0.72, 95% CI 0.59–0.89) and vomiting (RR 0.71, 95% CI 0.56–0.91). For example, in the 9 trials that compared P6 stimulation to antiemetic medication, P6 was superior in preventing nausea and equivalent in preventing vomiting. Electroacupuncture was reported to be effective for first-day vomiting after chemotherapy. Trials using noninvasive electrostimulation (primarily with wristwatch type devices) showed no benefit above and beyond control treatment with antiemetic medications.

Nicotine, Heroin, Cocaine, & Alcohol Addiction

There is good evidence suggesting that acupuncture is not effective in maintaining abstinence from nicotine addiction. A 2006 Cochrane systematic review of 24 trials concluded "there is no consistent evidence that acupuncture or acupressure, laser therapy or electrostimulation are effective for smoking cessation."

Despite insufficient evidence to support its use, auricular acupuncture is in widespread use throughout American drug treatment facilities. Although heroin, alcohol, and cocaine addiction studies have frequently reported positive outcomes, serious methodologic flaws have been found in these studies. A 2006 Cochrane systematic review of seven studies in which 1433 patients were treated with ear acupuncture for cocaine dependence concluded that there is currently no evidence to support its use.

Infertility

Conflicting results have been reported about the efficacy of acupuncture in improving the outcomes of women undergoing in vitro fertilization. A systematic review of seven clinical studies of acupuncture given with embryo transfer suggested that it may improve rates of pregnancy and live births. In contrast, a review of eight trials published later in 2008 concluded there were insufficient data that adjunctive acupuncture improved in vitro fertilization–related pregnancy rates.

Mind-Body Medicine

Definition

Mind-body medicine is commonly described as the field of medicine that uses processes of the mind to influence the health of the body. While this is a useful initial concept, it still can perpetuate the notion that mind and body are separate, and it fails to acknowledge the bidirectional relationship of mind and body (eg, exercise improves mood). It may be more accurate to think of *mind/body* as a single entity, with the health of one part necessarily influencing the health of the other. The NIH has defined mind-body medicine as "behavioral, psychological, social, and spiritual approaches to medicine not commonly used." This definition distinguishes mind-body medicine therapies from therapies that are more established or mainstream but that may have similar mechanisms of action (eg, psychotherapies, behavioral training, support groups, education). Traditionally defined mind-body therapies include biofeedback, hypnosis, meditation, guided imagery, relaxation techniques, yoga, tai chi, and chi gung.

History

The relationship between mind and body and its importance to health has been recognized for thousands of years by all major healing traditions, including the ancient Greek system that gave rise to modern Western medicine. With the ascendancy in the West of the scientific method and the biomedical model of illness, however, the relationship between mind and body has often been neglected. In the 19th century, interest in hypnosis began and later Freud championed the theory of the unconscious mind, which helped establish the paradigm that processes of the mind profoundly affect health. In the early 20th century, the American physiologist Walter Cannon began exploring the physiologic effects of emotional stimuli. In the 1930s, Dr. Clark Hull began studies of hypnosis, and research into hypnosis greatly expanded in the 1950s. The first biofeedback experiments also occurred in the 1950s. Since then, there has been considerable research evaluating mind-body phenomena and therapies. It has been established, for example, that certain emotions such as anger, anxiety, and depression affect clinical outcomes (including mortality) for conditions such as cardiovascular disease, cancer, and HIV infection. The new field of psychoneuroimmunology has documented, at the physiologic level, the powerful effect of the mind on the nervous, endocrine, and immune systems, and vice versa. Studies have demonstrated that certain forms of mental training, in addition to affecting health, can affect brain function and even structure, leading to a reevaluation of previously held beliefs about neuroplasticity.

Clinical Applications of Mind-Body Medicine

Mind-body medicine is popular. Over 20% of the US adult population has used one or more mind-body therapies in the past year. Data from the 2007 National Health Interview Survey show that use of most mind-body therapies has increased since 2002. The more conventional mind-body therapies already are established, supported by evidence, and widely available. For example, multimodal mind-body interventions that use some combination of cognitive behavioral therapies, support groups, education, relaxation and skills training have been proven effective for coronary artery disease, cancer, and chronic pain conditions. Mind-body therapies also work well as adjunctive treatments, for example with surgery, cancer treatment, and stress-exacerbated conditions (Table 41–4). They also offer the psychological benefit of increasing sense of control for the patient. Finally, mind-body therapies can be recommended because they have a very favorable safety profile.

Biofeedback

Definition

Biofeedback is a behavioral therapy method that teaches a patient to gain greater awareness and control over physiologic functions, including some not normally under conscious control. This is achieved by using technology that presents to the patient in visual or auditory form the level of activity of a physiologic parameter, such as muscle tension, skin temperature, sweat gland activity, respiratory muscle activity, PCO_2, heart rate variability, or brain wave pattern.

History

Biofeedback began in the 1950s with the work of the experimental psychologist Dr. Neil Miller. He demonstrated that rats could learn to regulate autonomic functions when motivated by painful or pleasurable stimuli. The idea that autonomic function could be volitionally controlled was contrary to the scientific dogma of the time. In the 1960s, other researchers began to examine the human ability to consciously alter physiologic function.

Training & Certification

Certification is obtained through the Biofeedback Certification Institute of America (BCIA) and is open to professionals from clinical health care areas including, but not limited to, psychology, nursing, and counseling. Requirements for certification are: (1) 48 hours of didactic education, (2) 20 hours of contact spent with a BCIA approved mentor, 50 patient/client sessions, and case conference presentations, and (3) successful completion of a written certification examination. There is also a continuing education requirement.

When treating a medical or psychological disorder, biofeedback practitioners are required to hold a current state license in a BCIA-approved health care field or, if without this license, work under the supervision of an appropriately credentialed health care professional. Separate, additional certificates are required for electroencephalographic (EEG) biofeedback (neurofeedback) and pelvic muscle dysfunction work.

Clinical Practice

Since biofeedback is a taught, self-regulatory skill, the patient should be motivated; prepared to take an active role in their treatment; respond well to visible, quantifiable information; or have aptitude or familiarity with technology. Typical biofeedback sessions last 50 minutes, with half or more of that time in active monitoring. To begin a biofeedback session, the therapist applies sensors to the patient that monitor the physiologic parameters of interest. For example, in a case of chronic tension headache, an electromyographic (EMG) sensor may be applied to the skin of the forehead. Information from the sensor feeds back to the patient as sound or as an image on a computer screen in real time, so he or she can begin to learn to reduce tension in the forehead muscle. Multiple sessions are usually required and the patient is asked to practice the learned skills between sessions. The goal of biofeedback is to help the patient train himself to produce the desired response at other times. Some biofeedback software programs and sensors are available for use on a home computer or with portable electronic devices.

Adverse Events & Contraindications

There are no reported adverse effects of biofeedback therapy. Benzodiazepines, opioids, other sedating medicines, and even caffeine can sometimes impair the efficacy of biofeedback training.

Clinical Uses of Biofeedback

Hypertension

Studies on the blood pressure lowering effect of biofeedback have been published for over 40 years. Meta-analyses consistently show that compared with wait-list or other inactive control groups, biofeedback can significantly lower patients' systolic and diastolic blood pressures (approximately 5–8 mm Hg systolic and 3–5 mm Hg diastolic pressure). However, when biofeedback is compared with active control group (eg, sham biofeedback or nonspecific behavioral control), it is usually not statistically superior in its effect on blood pressure except when coupled with relaxation training or cognitive therapy. One exception is a randomized controlled trial that compared active biofeedback to sham biofeedback and found significant reductions in systolic and mean blood pressure at 12-week follow-up. This study used direct blood pressure biofeedback, although the literature taken as a whole favors thermal and electrodermal (galvanic skin response) biofeedback methods over EMG or direct blood pressure biofeedback methods. In general, the degree of blood pressure reduction with biofeedback strongly correlates with pretest blood pressure. Persons with higher baseline blood pressures show larger beneficial effects from biofeedback.

Because most patients in studies of nonpharmacologic treatment of hypertension have only mild hypertension, the effect of treatments like biofeedback may be more difficult to detect. Also, it is worth noting that, as is the case for all antihypertensive therapies, small reductions in blood pressure yield important clinical benefits.

Also noteworthy in recent years is research on respiratory biofeedback training, in contrast to traditional thermal or electrodermal biofeedback methods for blood pressure reduction. A particular pattern of device-assisted respiration practiced for 15 minutes daily has been shown in seven of eight small studies to lower ambulatory blood pressure. In 2002, the FDA approved a simple device (RESPeRATE) to enable respiratory training for home use.

Coronary Artery Disease

There have been clinical studies of the effect of biofeedback on heart rate variability. Heart rate variability is considered to be an indicator of autonomic tone and has been postulated to be the mediator of the effects of cognitive and mind-body therapies on cardiovascular conditions. Cardiac electrophysiology studies have shown that poor heart rate variability is predictive of both short-term and long-term mortality after myocardial infarction. One randomized controlled trial of 63 patients with established coronary artery disease showed that biofeedback significantly increases heart rate variability. Another randomized controlled trial showed an 86% reduction in post-myocardial infarction mortality at 2 years from a psychosocial intervention that included biofeedback training of heart rate variability. However, this study did not show a significant change in heart rate variability with the intervention unless individuals with high heart rate variability at baseline were excluded. Thus, it remains unanswered whether improved heart rate variability from biofeedback training indeed affects important cardiovascular outcomes.

Raynaud Phenomenon

There have been seven randomized controlled trials of the efficacy of biofeedback on Raynaud phenomenon. Two show biofeedback to be superior to active control (eg, autogenic training), and four show benefit from biofeedback but equal to active control. One large study showed thermal biofeedback to be equivalent to EMG biofeedback treatment and to treatment with sustained-release nifedipine. However, there was a nonsignificant trend showing superiority of nifedipine over thermal biofeedback.

Headache

Biofeedback and other behavioral techniques have been extensively studied in prevention of recurrent migraine and tension headaches, with more than 50 studies including many randomized controlled trials. Several meta-analyses concur there is a significant reduction (30–55%) in headache frequency with biofeedback and other behavioral interventions. Other outcomes with significant improvement in several studies are anxiety, depression, self-efficacy and medication usage. The American Academy of Neurology practice guidelines state that there is grade "A" evidence for the use of thermal biofeedback with relaxation or EMG biofeedback for prevention of migraine. Biofeedback compares favorably with pharmaceutical treatments in several studies. There are also studies showing enhanced efficacy from adding medications to biofeedback therapy. The American Academy of Neurology practice guidelines state that there is grade "B" evidence for behavioral therapy (eg, biofeedback and relaxation techniques) when combined with prophylactic drug therapy (eg, propranolol and amitriptyline) to achieve additional clinical improvement for migraine relief.

Urinary Incontinence

There are at least 20 randomized controlled trials of biofeedback for stress, urge, and mixed types of incontinence in mostly postmenopausal women. In all of these trials, biofeedback produced improvement in symptoms; however, when compared with other treatment methods (eg, assisted or unassisted pelvic floor muscle training, use of vaginal cones), biofeedback was superior in less than half of these trials. It could be argued, however, that methods such as assisted pelvic floor muscle training or the use of vaginal cones are themselves forms of biofeedback. Therefore, while it is clear that training of the pelvic muscles is beneficial for reducing incontinence, it is less clear whether biofeedback-enhanced pelvic floor muscle training offers a significant advantage. The same conclusion can be drawn from the 11 randomized controlled trials of urinary incontinence in post-prostatectomy men, which show a benefit for pelvic floor muscle training whether assisted by biofeedback or not. Also noteworthy is a recent secondary analysis of an ongoing study of biofeedback for urinary incontinence, which importantly showed not only improvement in continence but also significant reduction of depression.

Fecal Incontinence

There are more than 40 experimental trials of biofeedback for fecal incontinence in adults and all but 2 of these report moderate to large benefit. However, the methodologic quality of many of these publications is low. A 2006 Cochrane review of biofeedback and sphincter exercises for fecal incontinence included 11 randomized controlled trials and concluded that the efficacy of biofeedback for fecal incontinence remained in question. Nonetheless, many authors and clinicians in this field consider it a first-line therapy. A report of 513 consecutive patients seen at a tertiary colorectal referral clinic showed that more than 70% of patients received benefit. American College of Gastroenterology Practice

Guidelines consider biofeedback safe and effective and recommend it for treatment of fecal incontinence.

Chronic Constipation

About 30–50% of cases of chronic constipation are due to pelvic floor dyssynergia, a failure of the pelvic floor and anal muscles to relax during straining. Pelvic floor dyssynergia may be less amenable to laxative and fiber treatment but appears to be successfully treated with biofeedback. This indication has been studied in adults in at least nine randomized controlled trials. In three trials, biofeedback was superior to sham biofeedback, polyethylene glycol, diazepam, and placebo. Because of its success rate (70–80%) and safety, biofeedback is widely recommended as first-line therapy alone or in combination with other measures.

Stroke Rehabilitation

Biofeedback for stroke rehabilitation has been difficult to evaluate for several reasons, including nonstandardized outcome measures and variability in the time post-stroke at which biofeedback is offered. There are over 20 randomized controlled trials, all with small sample sizes. Some individual studies show benefit in motor strength, gait quality, and functional recovery with EMG biofeedback. A Cochrane review concludes EMG biofeedback cannot be recommended as a routine treatment but due to its safety and possible efficacy its use can be reasonably considered.

Psychiatric Disorders

EEG biofeedback, also known as neurofeedback, was first used to reduce seizure frequency in epilepsy in the 1970s. Since then, it has been applied to attention-deficit hyperactivity disorders, anxiety disorders, affective disorders, substance use disorders, other psychiatric conditions, and traumatic brain injury. However, there are still few methodologically rigorous trials investigating this form of biofeedback. A recent pilot study suggests that a portable heart-rate variability biofeedback device produces additive benefit when combined with cognitive behavioral therapy (CBT) for patients with anxiety disorders.

Asthma

Evidence for the efficacy of biofeedback in asthma is tentatively favorable. Of the 11 small, randomized controlled trials, 5 show clear and significant benefit for clinical (eg, frequency of attacks, medication use) and physiologic (eg, peak expiratory flow, respiratory resistance) parameters, 3 fail to show benefit, and 3 have mixed results. EMG, PCO_2, heart rate variability, and trachea noise methods have all been used.

Hypnosis

Definition

Hypnosis is a procedure that induces an altered state of consciousness in which the patient's mind is more accepting of suggestion. It is believed that during hypnosis the usual evaluative, critical function of the conscious mind is bypassed and more direct communication with the subconscious mind occurs.

History

Hypnotic phenomena, including trancelike states for medical purposes, have been practiced around the world throughout human history. It was the Scottish surgeon, James Braid, in 1843, however, who coined the term "hypnosis" and laid the foundation for the use of hypnosis in modern medicine. Braid believed the effects of hypnosis were mediated by the mind of the patient. Important early research was conducted in the 1930s by Dr. Clark Hull and his student, Dr. Milton Erickson. In the mid-1950s, the British and American Medical Associations suggested that hypnosis be incorporated into the medical curriculum. In 1960, the American Psychological Association endorsed hypnosis as a branch of psychology. In 1996, an NIH Technology Assessment Panel judged hypnosis to be an effective intervention for alleviating pain.

Mechanism of Action

The mechanism of action of hypnosis has not been fully elucidated, but its effects are seen at multiple levels, including somatosensory cortex, anterior cingulate cortex (modulation of pain affect via limbic system), spinal cord and autonomic nervous system (eg, hypnosis can reduce colonic motility in irritable bowel syndrome). Additional recent evidence of mechanism includes upregulation of immune-related gene expression (eg, effects on tumor necrosis factor [TNF]-) and reduction of mucosal inflammatory response in ulcerative colitis. Hypnotic trance is a state distinct from sleep or relaxation, and hypnotic analgesia is distinct from placebo analgesia.

Training & Certification

Certification for hypnosis, granted through the American Society of Clinical Hypnosis, has the following requirements: (1) health professional degree, (2) 40 hours of workshop training, (3) 20 hours of supervised clinical training, and (4) 2 years of independent practice using clinical hypnosis.

Other certification programs exist. Patients and clinicians should inquire about the training and certification of any practitioner of hypnosis because there are no restrictions limiting its use to licensed health care practitioners.

Clinical Practice

The procedure of hypnosis can be divided into three phases: induction (or pre-suggestion), suggestion, and post-suggestion. The induction of a trance is accomplished in a variety of ways with the intention of developing relaxation and focused attention. Once the trance is induced, therapeutic suggestions are offered. In the post-suggestion phase, the patient returns to their usual state of consciousness and the suggestions may be discussed and reinforced. Self-hypnosis may be taught to further reinforce the therapeutic suggestions between sessions.

Although most people can respond to hypnosis, there is great variability in hypnotic susceptibility ("suggestibility") in the population. This can be measured with standard instruments such as the Harvard Group Scale of Hypnotic Susceptibility and the Stanford Hypnotic Susceptibility Scale. Studies have shown a positive correlation between hypnotic susceptibility and its efficacy.

The ideal candidate for hypnosis is a patient with high suggestibility and motivation, with a condition for which hypnosis has proven benefit. Course of treatment can vary from a single session to several. Sessions are usually 45–60 minutes, with the first session typically lasting 90–120 minutes. It is helpful when referring patients to dispel common myths about hypnosis. For example, it is not true that one loses consciousness in trance nor that one cedes control to the hypnotist. Trance state may best be described as a voluntary state of mind not unlike the one experienced when absorbed in reading a book or when daydreaming. It may be useful to explain to patients that the purpose of referral to hypnosis is to learn skills to use the mind-body connection.

Adverse Events

Adverse events from hypnosis have not been well studied. As with any psychological therapy, distressing emotions or thoughts may occur. These can manifest as somatic symptoms, such as dizziness, headache, or nausea. Occasionally, uncovering repressed psychic content can evoke strong emotional response, known as abreaction. A minority of hypnosis practitioners believe abreaction is therapeutic. Also, as with other mind-body medicine modalities that include deliberate relaxation, paradoxical anxiety reactions can rarely occur.

Contraindications

There is no consensus on contraindications to hypnosis; however, the use of hypnosis in patients with severe psychiatric disease is controversial. Also, patients who have very low scores on hypnotic susceptibility scales are less likely to derive therapeutic benefit.

Clinical Uses of Hypnosis

Pain

There are at least 40 controlled studies of variable methodologic quality on the use of hypnosis for treating acute pain in adult and pediatric populations. All but 3 studies show superiority of hypnosis over a control condition (usual care, no treatment, or attentional control). Hypnosis has been shown effective for peri-procedural and perioperative pain in patients undergoing breast lumpectomy, excisional and core breast biopsy, bone marrow aspiration, pectus excavatum repair (Nuss procedure), percutaneous transluminal coronary angioplasty and other percutaneous vascular and renal procedures, burn wound care, and plastic surgery. Many studies also report less procedure-related anxiety and lower analgesic medication requirement.

Cancer-related Symptoms

There are at least four randomized controlled trials specifically evaluating the efficacy of hypnosis for cancer-related pain and anxiety in adults. All four trials show benefit compared with no treatment or usual care. In addition, two of three randomized controlled trials show significant benefit of hypnosis for reducing anticipatory nausea and vomiting from chemotherapy. Other recent randomized controlled trials concluded (1) hypnosis decreased hot flash scores by 68% in breast cancer survivors; (2) self-hypnosis plus empathic attention was superior to empathic attention alone (for reducing pain, anxiety and medication usage) in 201 patients undergoing percutaneous tumor treatment; and (3) hypnosis preoperatively reduced institutional costs for breast cancer patients.

Irritable Bowel Syndrome

There are 14 studies of hypnosis for irritable bowel syndrome, 6 of which are controlled (placebo pill, CBT, or wait-list control). All 6 controlled studies show reduction in pain and bowel symptoms and some show improved quality of life and reduced anxiety. There are also 3 follow-up studies showing maintenance of benefits for 1 to 5 years in duration. The American College of Gastroenterology recommends behavioral therapies including hypnosis for the treatment of irritable bowel syndrome.

Smoking Cessation

A Cochrane review of 9 trials, distilled from a literature of over 50 studies, concluded that hypnosis is ineffective for smoking cessation. However, a more recent randomized controlled trial comparing hypnosis plus nicotine patch with behavioral counseling plus nicotine patch showed superiority of hypnosis, especially in those with a history of depression.

Mindfulness Meditation

Definition

Meditation is broadly defined as the self-regulation of attention. There are two general types of meditation: mindfulness meditation and concentration meditation. In health care settings, the most widely available form of meditation is the mindfulness-based stress reduction (MBSR) program. This program was specifically designed for medical populations.

The essential exercise of meditation is focusing one's full attention on a designated object of meditation, such as one's breath. When it is noticed that the mind has wandered from this object, attention is returned to the object. Training the mind, beginning with this basic exercise, has many effects including relaxation, metacognition, and revelation of previously subconscious content. In mindfulness meditation, after initial training with the breath, the objects of meditation can include other aspects of human experience, such as physical sensations (eg, pain) or mental and emotional states (eg, anxiety).

History

Mindfulness meditation originated 2500 years ago in northern India from the tradition of Buddhism. It is a deliberate, sustained, nonjudgmental way of paying attention to one's experience that is said to enhance self-awareness, change maladaptive thinking, increase the capacity for skillful response to challenges, and reduce suffering. In 1979, mindfulness meditation practice was first introduced into American medical settings with the development of the MBSR program by Dr. Jon Kabat-Zinn. MBSR is an intensive 8-week program that introduces mindfulness practice in a secular, practical form to participants in the context of their life circumstances. There are now over 250 MBSR programs throughout the United States and many in other countries throughout the world. More recently, a close derivative of MBSR, mindfulness-based cognitive therapy (MBCT), has been developed exclusively for people with recurrent major depression. Mindfulness has also been adapted for use in programs for borderline personality disorder (Dialectical Behavior Therapy), eating disorders, substance abuse, and childbirth preparation.

Mechanism of Action

There have been extensive cardiac, respiratory, metabolic, endocrine, and functional central nervous system studies of individuals during meditation. Though much remains unknown, it is clear that meditation works in part through modulation of the autonomic nervous system, and that its effects are different from and more complex than simple relaxation. From a psychological perspective, it is thought that meditation enables the mind to establish a stable platform from which all events in the field of awareness can be viewed (eg, emotions, thoughts, physical sensations) without reactivity. At the psychological level, proposed mechanisms of mindfulness meditation include metacognition, exposure, uncoupling of maladaptive thoughts from physical stimuli (eg, pain), enhancing cognitive flexibility, relaxation, self-regulation, and reperceiving. At the physiologic level, studies of mindfulness meditation have found effects on the immune system (increased antibody response to vaccination, reduction in proinflammatory cytokines, possible slowed decline of CD4+ lymphocytes in HIV disease), nervous system (enhanced cortical thickness in specific brain regions, enhanced left prefrontal activation on EEG, characteristic functional MRI findings), and endocrine system (reduced cortisol, increased melatonin levels). There is evidence of a dose-response relationship with mindfulness meditation.

Training & Certification

Certification is not required to teach MBSR, but in 2005 the Center for Mindfulness at the University of Massachusetts Medical School, where MBSR began, established a professional certification program. Ideally, an MBSR teacher should have a long-standing daily mindfulness meditation practice, a history of silent meditation retreats, experience leading groups, and a health professional degree.

Clinical Practice

The best candidate for an MBSR program is someone who is motivated and has a medical, surgical, or psychiatric condition with a significant component of psychological distress. Motivation is essential for two reasons. First, participation in an MBSR program requires as much as 28 hours of classroom time over 8 weeks (including an all-day silent retreat) and 30–45 minutes of formal guided mindfulness practice each day. Second, an important part of mindfulness practice is to directly explore any unpleasant physical or mental experiences as they arise. Often, MBSR programs offer free informational sessions that precede the 8-week series so patients can evaluate the program before they decide to enroll.

Adverse Events

There are no adverse effects of mindfulness meditation specifically reported in experimental trials, but meditation can allow previously subconscious, distressing psychic content to come into consciousness. Patients with psychiatric disorders should consult with a mental health care professional before starting a program of meditation.

Contraindications

Untreated psychosis, mania and intoxication from active substance abuse are relative contraindications because these conditions may impair the fundamental exercise required for mindfulness training (ie, repeatedly returning one's attention to a desired object of awareness).

Clinical Uses of Mindfulness Meditation

There are over 60 experimental trials assessing mindfulness-based interventions, approximately half of which are controlled trials. Most of the research examines the efficacy of MBSR programs, but there are also studies of MBCT, shorter mindfulness interventions and vipassana residential retreats. Two meta-analyses of MBSR show average effect sizes of 0.5–0.6.

Cancer-Related Symptoms

There are 15 studies of mindfulness meditation in patients with cancer, including 4 randomized controlled trials. All 11 studies that measured psychological variables showed significant improvement (mood disturbance, anxiety, symptoms of stress, quality of life). Two studies assessed sleep problems and both found improvement. In a nonrandomized comparison of MBSR and a healing-through-creative-arts program, the mindfulness intervention was superior in reducing symptoms of stress, anxiety, mood disturbance, and increasing sense of spirituality. The two groups were equal in increasing a measure of posttraumatic growth. Two other cancer studies showed that psychological benefits from MBSR were sustained at 6-month and 12-month follow-up, respectively. Interestingly, the first inpatient study of a mindfulness intervention, an uncontrolled pilot study of 20 adults undergoing hematopoietic stem cell transplantation, showed reduced pain, anxiety, and physiological arousal from pre- to post-intervention.

Depression

Four studies, two of which are randomized controlled trials, specifically examined the effect of MBCT on patients with major depression and demonstrated relapse reduction of almost 50% in patients who have a history of more than two relapses. One uncontrolled study of MBCT showed that the measured level of mindfulness attained after the intervention successfully predicted depression relapse. An additional randomized controlled trial of MBCT showed improvement in depression and anxiety for bipolar patients with suicidal ideation or behavior. A pilot study using MBCT for 51 patients with treatment-resistant depression (defined as two or more adequate trials of antidepressants) found significantly decreased depression and anxiety levels. A randomized controlled trial of MBSR for women with fibromyalgia showed improvement in depression maintained at 2-month follow-up. Multiple other MBSR studies show improvement in mood in various populations; however, two studies found mindfulness interventions to be equal to comparison groups (CBT and relaxation therapy) and a 2007 review of 15 of these studies concludes overall evidence of benefit is equivocal.

Anxiety Disorders

Two early uncontrolled studies specifically examined the effect of MBSR on patients with anxiety disorders and found significant benefits that were maintained at 3 year follow-up. Two uncontrolled studies examined MBCT for generalized anxiety disorder and found pre-to-post changes in anxiety but in one study the effect size was less than that commonly found in CBT studies. A randomized controlled trial of MBSR versus cognitive behavioral group therapy for social anxiety disorder showed cognitive behavioral group therapy was more effective at reducing symptoms of social anxiety; however, the CBT intervention was 50% longer in duration and results for functionality, quality of life, and mood were equal in the two groups. A randomized controlled trial of 31 pregnant women showed reduction of anxiety, perceived stress, and an improvement in mood. A small controlled study showed a significant reduction of symptoms in patients with obsessive-compulsive disorder. An uncontrolled study of adults and adolescents with attention deficit hyperactivity disorder showed significant benefit with MBSR; however, an intensive 10-day mindfulness (vipassana) retreat did not improve symptoms of posttraumatic stress disorder in an incarcerated population.

Fibromyalgia

There are four studies of mindfulness interventions for fibromyalgia, including two randomized controlled trials. All four studies show improvement in psychological measures; three showed improvement in pain, although one of the randomized controlled trials did not find MBSR to be superior to an education and support comparison group. One study showed maintenance of most benefits (pain, quality of life, anxiety, depression) at 3-year follow-up.

Other Chronic Pain

Seven studies, including almost 700 patients, have been conducted using MBSR in chronic pain populations. All studies showed significant improvement in mental health parameters, such as quality of life, acceptance, pain tolerance, and mood. Six of these studies (three controlled, three uncontrolled) showed pain reduction. One follow-up study showed that improvements were maintained up to 4 years later. A randomized controlled trial of MBSR for patients with rheumatoid arthritis showed improvement in psychological distress and well-being at 6-month follow-up, but no improvement in disease activity. A second randomized controlled study of patients with rheumatoid arthritis compared a mindfulness-based intervention (that was much less intensive than standard MBSR) with a CBT intervention and an education control group. Both experimental groups were significantly superior to the control group, although overall the CBT group showed the greatest reduction in pain and IL-6 levels. In the subset of patients with a history of recurrent depression, however, the mindfulness-based intervention yielded greatest reduction in pain and improvement in mood. Interestingly, a comparison of distant (via videoconferencing) versus on-site mindfulness-based programs for chronic pain showed significant gains for both groups, but the on-site group rated superior in physical quality of life and pain reduction.

Other Conditions

Other studies have been conducted on organ transplant recipients, patients suffering from psoriasis, tinnitus, type 2 diabetes, eating disorders, women with sexual arousal disorder, inner city residents, nursing home residents, incarcerated individuals, smokers, nurses and nursing students, college students, and medical students. Nearly all of these studies showed mental health benefit from mindfulness meditation and most showed index symptom reduction. Interestingly, a randomized controlled trial of psychotherapists in training showed improvement in the patients of those therapists who were taught mindfulness.

Guided Imagery

Definition

Guided imagery uses the imaginative capacity of the mind to affect one's physical, emotional, or spiritual state. As is the case with psychotherapeutic techniques, guided imagery can be applied in a variety of ways. It may be directive, with the therapist providing specific images, or it may be more receptive, inviting the patient to find their own images. It may be supportive, with the intention to create a relaxed, pleasant or specifically positive feeling (eg, trust or patience) or it may intend to directly work with an area of active challenge (eg, anxiety or pain). Classically, in guided imagery, the therapist is less directive and the patient has a more active role than in hypnosis; however, this distinction is not always true in clinical practice and guided imagery can closely resemble hypnosis, especially when suggestion is used. Guided imagery can be conducted live with a therapist one-on-one, in a group setting (less common), or via audio recording.

History

Imagery has been used throughout history and can be found in the origins of all ancient healing systems still extant today. In contemporary Western medicine, the psychiatrist Dr. Carl Jung recognized the importance of imagery as an expression of the subconscious and in 1915 developed a psychotherapeutic technique called "active imagination." With the similar intention to aid psychoanalytic exploration, the French psychotherapist Dr. Robert Desoille in the late 1930s created a method he called "directed daydreaming," and in the 1950s Dr. Hanscarl Leuner introduced "guided affective imagery." Medical research on guided imagery began in the 1970s and increased greatly in the 1980s. In 1989, the physician Dr. Martin Rossman and the psychologist Dr. David Bresler founded the Academy for Guided Imagery which began certifying health professionals. In recent years, some health insurance companies and surgical programs have been providing free guided imagery recordings for patients undergoing surgery.

Mechanism of Action

The mechanism of action of guided imagery is not well known, but some physiologic effects have been demonstrated. Three of five studies examining cortisol levels in relation to guided imagery have found that serum levels decreased after the intervention. Studies of the effect of guided imagery on immune function have shown mixed results. However, a recent randomized controlled trial of women with breast cancer showed increased NK cell cytotoxicity and increased IL-2-activated NK cell activity. One study documented reduced physiologic arousal around chemotherapy sessions, as measured by heart rate and systolic blood pressure. Some proposed psychological mechanisms postulated to explain the effects of guided imagery include cognitive restructuring, increased sense of control, increased adaptive coping, distraction, and relaxation.

Training & Certification

The leading certifying organization, the Academy for Guided Imagery, generally limits certification to licensed health care professionals or health professional students, but exceptions are allowed. To obtain the certification known as "interactive guided imagery," 150 total hours of training is required, including 52 hours of small group supervision. Applicants are also required to adhere to the American Psychological Association code of ethics. Another certifying organization is Beyond Ordinary Nursing, which requires 110 total hours of training, including ten documented imagery sessions.

Clinical Practice

The length of a typical guided imagery session with a therapist is 50 minutes, with 20–30 minutes spent in active imagery. The imagery portion of the appointment often begins with imagining a place of comfort and safety, then proceeding to the desired area of specific clinical attention. Polysensory recruitment is often used (ie, the patient is asked to imagine visual, auditory, tactile, olfactory cues in imagining the safe place and then in focusing attention). Examples of specific clinical techniques used by the therapist might include dialoging with the symptom ("If your back pain had a voice, what would it say?"), consulting a wisdom figure or inner advisor ("What does your wisdom figure say about how to approach this cancer treatment?"), and visualizing a desired outcome ("Imagine yourself waking up after surgery feeling calm and comfortable."). Interactive Guided Imagery is a type of imagery that more deliberately aims to enhance awareness of subconscious content.

Predictors of favorable outcome from guided imagery, based on three studies, are previous experience with guided imagery, imaging ability of the patient, perceived credibility of the therapist, and rapport of the patient with the therapist. Age, gender, and education level have not shown significant correlation with outcomes, suggesting that this technique can be applied widely.

Adverse Events

Adverse events have not been reported with guided imagery. However, as is the case with any psychotherapeutic technique, distressing psychological content can arise.

Contraindications

There are no contraindications based on outcomes studies. However, due to the potential risk of reexperiencing original trauma, caution is advised in using guided imagery in patients with posttraumatic stress disorder or history of severe trauma or abuse.

Clinical Uses of Guided Imagery

Surgery

There are many studies examining the use of guided imagery on outcomes related to such surgeries and procedures as heart surgery, colorectal surgery, abdominal surgery, laparascopic gynecologic surgery in adults, bone marrow aspiration, lumbar puncture, burn wound debridement, and administration of immunizations in children. Although many of the studies have methodologic limitations, reviews and meta-analyses have found overall benefit of small to moderate effect sizes for reducing psychological distress and reducing postoperative pain. However, a randomized controlled trial of guided imagery for peri-procedural pain and anxiety conducted with 170 women undergoing colposcopy did not show a significant effect. Two of the three randomized controlled trials assessing its effect on average length of hospital stay found a significant decrease with guided imagery intervention. Other studies have shown significant decreases in total opioid use and average pharmacy costs.

Cancer-related Symptoms

Most of the studies in patients with cancer use guided imagery in combination with another modality, such as progressive muscle relaxation, meditation, hypnosis, biofeedback, or music therapy. These studies vary in methodologic quality. There are at least 18 randomized controlled trials in this category and all show benefit for psychological outcomes, such as quality of life, anxiety, and depression. Studies that assessed the effect of guided imagery in combination with other modalities on nausea and vomiting also showed uniform benefit for this symptom. With respect to nonprocedural, cancer-related pain, there are at least 6 randomized controlled trials using guided imagery as part of a combination intervention. Three studies showed significant pain reduction with guided imagery intervention, 2 showed no pain reduction, and 1 showed significant benefit in patients' self-reported ability to decrease pain but not in measured pain intensity.

There are also several randomized controlled trials of guided imagery as a sole adjunctive treatment for patients with cancer. All of these studies again showed that guided imagery led to improvement in psychological outcomes, and in approximately half of the studies, the improvement was superior to other comparison interventions, such as progressive muscle relaxation or hypnosis. The evidence for guided imagery alone in preventing chemotherapy-related nausea and vomiting is mixed.

A single study has examined the effect of guided imagery directly on cancer disease regression using clinical (UICC criteria) and pathologic (biopsy) measures and found no effect.

Chronic Pain

There are several studies of guided imagery for various chronic pain conditions, such as osteoarthritis, headache, low back pain, fibromyalgia, and interstitial cystitis. Some of the studies are controlled and all show benefit in either pain, psychological distress, or both.

Stroke Rehabilitation

Four randomized controlled trials report efficacy of motor imagery for rehabilitation post-stroke.
